IN MEMORIUM
JOHN CARL MEDCOF
1911–1997

J. Carl Medcof, a well-known and highly respected authority in the field of molluscan biology, oyster biology, and shellfish management in Atlantic Canada, died on 28 February 1997, in St. Andrews, New Brunswick. He was 86 years old.

Carl was born into a family with a strong academic background in Ruthven, Ontario in 1911, and the family moved soon after his birth to Toronto. His father, stepmother (his mother died when he was quite young), and uncles were all teachers. He received his elementary and secondary education mostly in Toronto and enrolled in the University of Toronto, where he received his B.A. in biology in 1932. He received an M.A. degree from the University of Western Ontario in 1934, undertaking a study of a snail, *Campeloma*, in a small river in southern Ontario as his thesis topic. Thus, began his lifelong interest in the field of molluscan biology. He received his Ph.D. degree from the University of Illinois in 1938, studying under Dr. H. J. Van Cleave, who was very influential in his early career. While at the University of Illinois, he was elected to the Phi Beta Kappa Society.

During his senior year at the University of Toronto and throughout his graduate years, Carl served as a teaching assistant. He maintained a keen interest in young people and always welcomed opportunities to talk with students and young scientists and encourage them in their work. He was a lifelong teacher, and many summer students benefited from his store of knowledge.

While an undergraduate, Carl began work as a summer student with the Biological Board of Canada, later the Fisheries Research Board of Canada. His first job was with investigations of Atlantic salmon. Subsequently, he worked as a summer student at Ellerslie, Prince Edward Island, where he came under the influence of Drs. Alfreda B. Needler for "red tides" and Alfred W. H. Needler, the director of the Station. Ellerslie was established to study oyster culture and foster development of the industry in the Canadian Maritimes. Thus, began Carl's enduring association with oyster research and the oyster industry of the Canadian East Coast. The title of his Ph.D. dissertation was "Studies on the larva of the Canadian oyster" and was focused on experiments with *Ostrea (Crassostrea) virginica* in the Bideford River, Prince Edward Island, Canada.

On completion of his Ph.D., Carl joined the staff of the Fisheries Research Board of Canada and was employed first at the Ellerslie Station, where he assumed responsibility for oyster research. He moved to the Biological Station in St. Andrews, New Brunswick in 1940, where he continued his work with oysters and also assumed responsibility for research work on all molluscan species including soft-shell clams, *Mya arenaria*, quahaugs, *Mercenaria mercenaria*, and sea scallops *Placopecten magellanicus* with his technician, Mrs. Esther Lord. Up until 1944, he moved with his family in the summers to Ellerslie and to St. Andrews in the winters.

Carl undertook a wide range of studies on oysters, including investigations on breeding to ensure a supply of juveniles for the industry, work to improve culture methods, and studies to improve harvesting and marketing. He maintained a close working relationship with the industry during his career, and much of his work focused on developing methods to improve it. He enjoyed working with people in industry and had their complete trust. Much of his work with oysters culminated with the publication, *Oyster Farming in The Maritimes*, which became a standard text for oyster culture in eastern Canada. This expertise took him to Cape Breton, Nova Scotia, where he worked with natives from the Eskasone Indian Band to grow oysters. He was also involved in experiments in the mid-1950s to transplant European oysters *(Ostrea edulis)* from France to the Bay of Fundy.

Carl worked extensively on the soft-shell clam with Mr. Stuart MacPhail from the Fisheries Research Board as well as with colleagues

from New England such as Mr. Dana Wallace. His clam work took him to eastern Nova Scotia, the Bay of Fundy, and the Gulf of St. Lawrence, where he worked with local harvesters to survey their areas and methods to increase production. He and Stuart MacPhail introduced the first water jet harvesters for soft-shell clams to the local industry and built prototypes for hand-held models as well as a vessel-equipped escalator harvester. Other clam species were studied as well. He and Ross Chandler from the St. Andrews Biological Station did the early biological work for the ocean quahaug clam fishery in southeast Nova Scotia.

Another major scientific contribution Carl made was in the field of shellfish toxins, particularly paralytic shellfish poisoning (PSP). As a result of his work and leadership, much of the history of PSP in the Canadian Maritimes was recorded and the etiology of outbreaks established. Results of this work led to establishment of a monitoring system for PSP to ensure that safe shellfish were marketed. Carl was the guest of honor at the Third International Conference on Toxic Dinoflagellates in 1985 and was awarded with a plaque in recognition of his contribution in this field. Later in his life, Carl said, "The most important work I did as a scientist was on resolving many paralytic shellfish problems. In addition I was able to work on methods of producing reliable forecasts about the expectancy of one of the major poisonous agents."

Carl also had a vision for the future. As early as the 1950s he was promoting the concept of aquaculture in marine production and was actively working on developing the protocols for producing soft-shell clams. He gave several media (including television) interviews and lectures on this topic. In addition to clams, he also predicted the development of the mussel culture industry in the Maritimes and an industry for sea urchin roe; something that is only just developing 25 years later.

Because of his expertise in shellfish, Carl was seconded to the Colombo Plan for 2 years in 1953 and 1955 and worked in Sri Lanka, assisting with development of invertebrate and other fisheries there. In 1955, he went to Europe to tour the various shellfish industries for information exchange with colleagues and for technology transfer. In the late 1960s, he undertook a similar trip to Japan with a group of Canadian scientists.

Carl retired from the Fisheries Research Board of Canada in 1973 and then spent a year in Australia, where he worked as a consultant to the shellfish industry through the University of Southern Australia in New South Wales. One project he undertook there was an investigation of the introduction of organisms via ballast water in ships, a subject that has become of great interest recently internationally.

Carl received numerous awards, both scientific and nonscientific, for the contributions he made during his lifetime. He was a long-standing member of the National Shellfisheries Association and served on the Editorial Board for the Proceedings and the Journal for many years. He was made an Honorary Member of the Association in 1973. He received a Centennial Medal from the Canadian Federal government in 1967 for his contributions to the Fisheries Research Board of Canada.

During his retirement, he taught a course in Marine Ecology at the Huntsman Marine Science Centre in St. Andrews. The course involved a rich mixture of basic biology, natural ecology, and the geological and paleological history of the Charlotte County area of New Brunswick.

Carl had a multitude of other interests and on his retirement began another career, recording the history of Charlotte County, New Brunswick, an offshoot of his previous hobby. He had long had an interest in the history of the area and in 1961 was a co-founder of the Charlotte County Historical Society, serving as its first president. He encouraged people to record what information they possessed of the area, and it was through his efforts as editor over a period of 21 years that an 12-volume collection of papers was published as *Contributions From The Charlotte County Historical Society*. As a result of his work with the Historical Society, Carl was presented with an Award of Merit from the Canadian Museums Association in 1981.

He was a devoted citizen of St. Andrews and took an active part in the affairs of the town, contributing to it in many ways over the years. During his lifetime, he was a Scoutmaster, Chairman of the Board of School of Trustees, a member of the local Kiwanis Club, and served as president. He was a member of the St. Andrews Anglican Church and published a history of that church. He served as vestryman, was an honorary church warden, and with his joy of singing, was a member of the church choir for many years. In 1987, the local Kiwanis Club selected him as their Man of the Year in recognition of his numerous contributions to the town.

Carl was a kind, gentle, humanitarian who brought out the best in people. He enjoyed working quietly, smoking his pipe (although more matches were burned than tobacco!), and he always had a package of dulse in his pocket, which he chewed and offered to anyone he met; he was one of the few people in the world who actually enjoyed chewing dulse! Those of us who were privileged to work under his direction will always remember the kind, thoughtful guidance and encouragement he gave us in our careers and his kind advice not only to be good scientists but to be good citizens. It was a joy to work and go on field trips with him, where we could enjoy his companionship and take part in long philosophical discussions on a wide range of biological and other topics.

Carl is survived by his wife of 55 years, Bessie, their three children, Susan, John, and Ranby, by three grandchildren, and by a great many people whose lives have been made more meaningful through their association with him.

ACKNOWLEDGMENTS

We thank Mrs. Esther Lord and Mr. Ross Chandler for reading an earlier draft of the manuscript and sharing their insights on Carl's life. We also thank Mrs. Bessie Medcof for helping us with the chronology of the events and her perspective on her husband. Marilynn Rudi of the St. Andrews Biological Station library kindly provided some of the historical information.

IN MEMORIAM
RUTH DIXON TURNER
1914–2000

Ruth Turner was born in Melrose, Massachusetts December 7, 1914. She attended Bridgewater State College, MA and graduated with a B.S. in 1936. She became a school teacher, teaching in both Bondville, Vermont and North Reading, Massachusetts before accepting the appointment of Assistant Director of Education at the New England Museum of Natural History (now the Boston Museum of Science). Ruth subsequently became Assistant Curator of Birds at the Museum, before moving to Vassar College as an Instructor in the Biology Department. During this same period she completed a M.A. at Cornell. By this time Ruth was an accomplished ornithologist, an interest that she maintained throughout her life. Indeed, it was her interest in birds that first lead her to the Museum of Comparative Zoology at Harvard. While serving as a volunteer in the Ornithology Department she met William J. Clench, Curator of Mollusks. Clench introduced Ruth to Dr. William Clapp, a pioneer in the study of marine wood borers, and in 1944 she moved to the William F. Clapp Laboratories in Duxbury, Massachusetts. It was here that her career as a malacologist became firmly established. She returned to Harvard University two years later to work with Clench.

Harvard remained her scientific home and a source of great pride to her throughout her career. One of her early field trips with Clench was to Cuba in 1949 to examine local terrestrial and marine mollusks. She received her Ph.D. from Radcliffe College, Harvard University in 1954. Her dissertation on the Teredinidae remains a standard work to this day. From 1954 through 1975 she served as Research Associate in the Department of Mollusks at the Museum of Comparative Zoology, Alexander Agassiz Fellow in Zoology and Oceanography, and Lecturer in Biology at Harvard. In 1976 she became Professor of Biology, Curator in Malacology at the Museum of Comparative Zoology, and joint editor of the scientific journal *Johnsonia*. Ruth received honorary D.Sc. degrees from New England College and Plymouth State College of the University of New Hampshire, and held honorary appointments at the Academy of Natural Sciences in Philadelphia, the Woods Hole Oceanographic Institution, the Gray Museum at the Marine Biological Laboratory at Woods Hole, Leigh University, CSIRO and the University of New South Wales in Australia, the University of Puerto Rico, and as an FAO Fellow in India. Ruth was honored by the Woods Hole Oceanographic Institution as a "Women Pioneer in Oceanography." On a lighter but no less important note, Ruth was named "Diver of the Year" by the Boston Sea Rovers, an educational society of which she was a very proud member. Ruth served terms as President of both the American Malacological Union and the Boston Malacological Club. She was a Honorary Life Member of the National Shellfisheries Association.

Ruth was a pioneer in the field of marine biodeterioration research, and enjoyed a long term relationship with the Office of Naval Research. This, combined with her work in invertebrate and larval ecology, took her to many corners of the globe including France, Belgium, Netherlands, England, Germany, Denmark, Puerto Rico, India, Pakistan, many locations in Australasia, South America, and the former Soviet Union. Although a leading researcher, she enjoyed teaching at all levels from special courses for public school teachers, to undergraduate and graduate teaching, to her gentle persuasion of fellow researchers to look at a problem or a data set in another light. Ruth's work also took her on many oceanographic cruises and to the depths of the ocean. On August 13, 1971, she became the first woman to dive in the deep submergence research vehicle ALVIN. This was the first of many dives and a deep sea career that included long term biodeterioration and species diversity work in the deep ocean (it was Ruth who explained why so little wood remained on the Titanic when it was found deep in the North Atlantic Ocean), and participation in multi-investigator cruises to the Galapagos Rift system.

Despite a career filled with discovery, innovation, and firsts, the most memorable component of Ruth's character that remains with the majority of people who met her is her warmth and friendliness, and her desire to show the excitement of science to all. Her love of science was effusive. She had a unique ability to share her science with audiences of all ages and skill levels. She was equally a superb teacher, illustrator, and practical scientist from fine work with the electron microscope to dissections of material from the field. Ruth taught and mentored many scientists at many levels, unselfishly giving of her time and energy to advance their careers. I consider myself fortunate to have enjoyed such direction from Ruth. Ruth shared much of her science through her publications, over 100 in all. Ruth worked actively until well after her 80th birthday. She left unfinished two major works, a monograph on her studies of deep sea borers and a comprehensive illustrated catalog of the pholads. Her colleagues have committed to finish these.

Throughout her career Ruth made unique contributions in malacology and deep sea biology. She was an internationally respected educator and researcher, an ambassador for marine and biodeterioration studies, and an outstanding role model for women in science. Ruth is survived by her sisters Winifred Garrity and Lina MacNeil. Ruth was predeceased by her brothers Henry and Arthur, and her sisters Jessie, Mary, and Frances. Ruth never married, but had a large extended family of colleagues and students. She will be sadly missed.

Roger Mann
Professor of Marine Science
School of Marine Science
Virginia Institute of Marine Science
College of William and Mary

Kenneth Kendall Chew
Honored Life Member

Dr. K. (Ken) K. Chew, is a recognised authority in the field of molluscan biology who has contributed extensively to invertebrate research and the continuing development of the shellfish industry on the west coast of North America. His contributions in the field of molluscan aquaculture are recognised world wide and his advice and consultation are frequently sought by industries in many countries.

Ken was born in Red Bluff, California in 1933 and received his elementary and secondary education there. While growing up, he worked in the family restaurant where he learned the fine art of Chinese cuisine. Those of us who have tasted Ken's cooking can attest to the fact that he mastered this fine art.

He obtained his B.A. from Chico State College in 1955 and then decided to attend the School of Fisheries of the University of Washington and become a fisheries biologist. Ken received a fellowship to begin graduate work on trout and salmon but Dr. Van Cleve sent him to the Washington State Department of Fisheries Shellfish Laboratory at Brinnon for the summer. He became involved in shellfish work at the lab and decided that his future lay with invertebrates, mainly molluscs, rather than fish and he entered the world of molluscan biology. He obtained his M.S. degree in 1958, studying the food preference of the Japanese oyster drill, and his PhD in 1962. The title of his PhD thesis was, "The growth of a population of Pacific oysters, *Crassostrea gigas*, when transplanted to three different areas in the state of Washington." His supervisor was Al Sparks, a former president of the National Shellfisheries Association.

After receiving his PhD, Ken joined the staff of the School of Fisheries at the University of Washington and has remained there since. He has held several positions at the School and has taught a variety of invertebrate courses. At present he is a Professor in the School of Fisheries. In 1989 he became the Director of the Western Regional Aquaculture Center (WRAC) which is one of five aquaculture centers designated by the U.S. Department of Agriculture to foster development of aquaculture in the United States. He resigned that position in 1996 to be the interim director of the School of Fisheries. He was then appointed Associate Dean, College of Ocean and Fisheries Sciences at the University of Washington in 1998, the position he holds presently. In addition to other duties, Ken is now busily engaged assisting with expansion of the College and seeking support for the College from industry.

Ken's research interests cover a wide spectrum that include shellfish biology and aquaculture, paralytic shellfish poisoning, and problems related to baseline ecological studies involving benthic intertidal and subtidal invertebrate communities. He has published over 100 papers on a wide range of shellfish subjects in scientific Journals, Technical Reports, Conference Proceedings, chapters of books and in columns of trade publications.

Teaching and maintaining a close rapport with students has been an important part of Ken's life and he has inspired many students to continue with studies in molluscan biology. During his career, about 100 students obtained graduate degrees under his supervision. In recognition of his outstanding teaching ability he received the 1993 Distinguished Undergraduate Teaching Award from the College of Oceans and Fisheries Sciences at the University of Washington.

Throughout his professional career, Ken maintained a close working relationship with the molluscan shellfish industry, particularly the industry in the Pacific Northwest. Much of his research and that of his graduate students focussed on finding solutions to problems to aid development of the industry. The present healthy state of the shellfish industry in the Pacific Northwest is due in a large measure to the efforts of Ken Chew and his co-workers. His talents and devotion to the shellfish industry were recognised when he was made Director of WRAC. In this position he devoted considerable time and energy testifying before Congressional Committees in Washington, DC on issues related to development of aquaculture.

Ken's influence in the shellfish industry has not been confined to the Pacific Northwest. He has provided advice and consultation to many countries throughout the world including; Australia, Canada, China, Chile, Japan, Thailand, Taiwan, Hong Kong and the Philippines. He has lectured on molluscan biology and culture in many countries. He was an invited guest lecturer in China and in 1987 was appointed for life as a visiting professor at Shandong College of Oceanography.

Ken has been actively involved with the National Shellfisheries Association since he first joined in 1958. He served on the Board, was Vice President from 1970–71, President from 1971–72 and served as an Associate Editor for the *Journal of Shellfish Research* from 1989–92. He has organized annual meetings held in Seattle. Another important function Ken has undertaken is to arrange Chinese Dinners at annual meetings. Many of us have enjoyed the fine cuisine and companionship that these evenings have afforded.

In addition to his involvement with the parent National Shellfisheries Association, Ken has played a major role to preserve and foster the association between the Pacific Coast Oyster Growers Association and the West Coast Section of the National Shellfisheries Association. From 1975–1990 Ken was the main reason this association survived and he devoted considerable time and energy into preserving this close association between industry and the scientific community of NSA. It is now a large and dynamic association and serves as an excellent forum for people from industry, government, and academia to come together and discuss shellfish work and problems. Many students have presented their first paper at these meetings. The present healthy state of this association is a monument to Ken's organisational skills and abilities.

As a result of his work and association with NSA, Ken was awarded the first David H. Wallace Award given by the Association in 1982 for his dedicated service in promoting research, understanding and co-operation among shellfisheries scientists, culturists, managers, producers and regulators. In further recognition of his contribution to NSA, he was elected to Honored Life Member in 1989.

Ken has been active in other organizations as well. He was a member of the Board of the World Aquaculture Society from 1973–76, President in 1977 and an associate editor of the Proceedings of the Society from 1985-89. He was editor for the North American Oyster Workshop that appeared as a special publication of the World Aquaculture Society in 1983. He received an Honorary Life Member award from the World Aquaculture Society in 1995. At present he is a columnist for Aquaculture Magazine.

Ken is an avid sportsman and, when time permits, relishes hunting and fishing. He is an excellent taxidermist and has mounted several species of birds he collected. He is a keen hand ball player and more than one meeting has been delayed so he could complete a game of hand ball.

Along with all his shellfish activities, Ken has found time to be an exemplary family man. He and his wife, Maegan, have raised four children and now have three grandchildren. They now have time to relax and enjoy their family and the view of Puget Sound from their wonderful house in Seattle. The shellfish world and NSA owe much to Ken Chew for his past contributions and his friends and co-workers know his influence will continue to be felt for many future years.

Victor Samuel Stuart Kennedy
Honored Life Member

Dr. "Vic" Kennedy, a long time NSA member, Vice President (1988–1989), and President (1990–1991), was born in Ireland in 1942. Although long established in the U.S., he still maintains a Canadian, United Kingdom citizenship. His early education was at Sir George Williams University in Montreal, Canada, where he received his B.Sc. in zoology (1962). He continued graduate education at Memorial University at St. John's, Newfoundland, with a M.S. in fisheries biology (1964). Vic then entered the University of Rhode Island for his Ph.D. where Dr. Paul Saila was his major professor.

I first remember Vic by a phone call in 1967, whereby he introduced himself and said Dr. Saila suggested he call me because of our Chesapeake work in thermal ecology. He expressed an interest in doing the same with a shellfish species at our Chesapeake Biological Laboratory's field station at Hallowing Point about 20 miles up estuary from CBL. I invited him down and vividly remember our lunch at old famous Shorter's Restaurant in Benedict on the Patuxent Estuary. He impressed me with his quick mind, familiarity with the literature, and obvious intense interest in aquatic and shellfish ecology. I hired him on the spot and offered a pre-doc position. I called Dr. Saila, (an old friend that first befriended me as a graduate student at an American Fisheries Society meeting) afterward. I thought a graduate student accepted by Saul was surely good enough for me too.

Vic completed his Ph.D. on the role of temperature on the soft shell clam, *Mya arenaria*, in 1970 and has maintained a peripatetic professional career. After completing his Ph.D., he was visiting Assistant Professor at Chapman College in California where among other activities he spent two semesters traveling the world and teaching on board their "World Campus Afloat" vessel. He came back to Maryland in 1972–73 to continue thermal research, then left in 1973 for a Post-Doc fellowship at the University of Canterbury in New Zealand where he taught and completed research on mussels. In 1974, a Post-Doc was accepted at Newfoundland Biological Station in St. John's where he investigated the role of arsenic in a marine food web and on benthic soft bottom communities.

In 1976 he returned to the University of Maryland System's Horn Point Laboratory as an Assistant Professor and continued his teaching efforts as well as benthic ecology research. Again he left the Maryland area in 1983, and spent a sabbatical year as a W. F. Jones Fellow at St. Francis Xavier University in Nova Scotia where he continued his benthic research and taught a marine ecology course. In 1984 he returned to the Horn Point Laboratory, was promoted to Full Professor in 1986 and named Assistant Director in 1989. Again he left Maryland on a sabbatical and served as visiting Professor on board the *SS Universe Campus*, University of Pittsburgh ship, for the Semester at Sea Program. Vic has remained at Horn Point since! Throughout all this substantial traveling (40 countries), teaching

and current administrative duties, Vic has continued a vigorous research program dealing with shellfish reproduction and larval behavior, as well as crustacean and fish foraging behavior as reflected in the selected publications listing. His activities have covered both the littoral and sublittoral benthic habitats and communities. His long term interest in thermal ecology has now evolved into the global climate change arena.

Vic has over 45 journal refereed publications, over 10 chapters in books and conference proceedings and 5 written or edited books. He enjoys a special reputation for his publication efforts dealing with morphology, biology, ecology, and management history of the eastern oyster, *Crassostrea virginica.* A most important current activity is completing editorship of a 13 chapter book on blue crabs, which he has been working on with Dr. L. Eugene Cronin. (See Vic's In Memoriam to Dr. Cronin in *J. Shellfish Res.* 18(1):1–3, 1999). Another substantial service he has provided to the research and management communities are publications of 5 extensive bibliographies that have covered the world's literature in their respected areas.

Concerning professional societies, Vic has assumed numerous responsibilities over the years, including President of the Atlantic Estuarine Research Society, with the aforementioned National Shellfish Association and a governing board member of the Estuarine Research Federation. He has had editorial responsibilities for the *Transactions of the American Fisheries Society, American Malacological Bulletin,* and *Estuaries,* among others. Vic's service also includes numerous requests for research proposal reviews by NSF, Sea Grant, Hudson River Foundation, and the Smithsonian Institution. Beyond his usual numerous editing services, he regularly undertakes requests for reviews on books dealing with aquatic and coastal habitats and processes. This extensive editing experience he has translated to a very popular graduate course entitled "Scientific Writing and Communication" in which his last class had 38 students, an almost unheard of number in a graduate course.

In addition to the W. F. Jones Fellow honor he also won as NSA Thurlow C. Nelson award in his junior investigator days (1968), was noted for outstanding service by AFS, and given an Honored Life Member Award by NSA in 1995.

Vic shows no sign of slackening in his science enthusiasm and his very active and diversified professional involvements. Indeed, with his two children off in Canada, one in the creative arts and the other with her family working with the native Inuits on Baffin Island, I suspect he may even pick up the pace if his wife Debbie will allow!

Sammy M. Ray
Honored Life Member

The scientific contributions of Dr. Sammy Ray to oyster disease research are widely acclaimed, due in no small part to the diagnostic method he developed to detect the disease agent *Dermocystidium marinum*. Dr. Ray was one of a handful of investigators in the early 1950's to explore this new oyster disease found in the Gulf of Mexico. Now the disease agent is called *Perkinsus marinus* and molecular techniques can be used to specifically diagnose the protozoan pathogen. Nonetheless, the highly reliable diagnostic technique developed by Dr. Ray is still the most widely used in oyster disease studies.

Dr. Ray was born in Mulberry KS, attended Mississippi Delta Junior College, Louisiana State University, and received his M.A. (Biology, 1952) and Ph.D. (Biology, 1954) degrees at Rice University in Texas. His postgraduate career began with the U.S. Fish and Wildlife Service as a Fishery Research Biologist and he joined the Texas A&M staff in 1957 at the Research Foundation Laboratory in Grande Isle, LA. He became an Associate Professor (1963) in Oceanography and Wildlife and Fisheries Science and was named Director of the Marine Laboratory at Galveston. As he reached Full Professor (1972), Dr. Ray was named Head of the Department of Marine Sciences. Since then he has held positions as Dean of the Moody College of Marine Technology and interim President of Texas A&M University at Galveston. Dr. Ray officially retired in 1990, but remains active as an advisor and coordinator of student programs and several community outreach programs.

Several academic honors have been awarded to Dr. Ray, including a Faculty Distinguished Achievement Award in Research at Texas A&M University at Galveston (TAMUG), the William Paul Ricker Award for Distinguished Faculty–Staff Achievement (TAMUG), a Distinguished Alumnus Award from the Mississippi Delta College, and a Piper Professor Award. He was awarded a lifetime honorary membership in the National Shellfisheries Association at the 1990 meeting in Maine.

Dr. Ray has been a reliable source of scientific information and advice for the State of Texas for many decades. He remains actively engaged in the interpretation of scientific knowledge for competent management decisions related to oyster and shrimp fisheries in the Gulf of Mexico. He has, over the last 10 years, participated in both the Joint Interim Committee on the Texas Shrimp and Oyster Industry and the Gulf of Mexico Fishery Management Council. Dr. Ray is a past chair of the Scientific and Technical advisory Committee for the Galveston Bay National Estuary Program and is a member of the Board of Trustees of the Galveston Bay Foundation.

Perhaps the most rewarding achievement of this exceptional career is the initiation of Sea Camp, "a hands-on marine adventure" for summer students aged 10–16, currently sponsored by TAMUG and the Texas Sea Grant College Program. Students attending the 5-day camps are given the opportunity to explore the Galveston Island area in research vessels, visit laboratory facilities and use scientific equipment to study marine organisms. Dr. Ray served as Director of the Sea Camp until 1993 and, in a similar capacity, is the Director of the Community & Youth Program for TAMUG. Dr. Ray and his wife Charlotte, an accomplished pianist now playing organ for the St. Luke's Episcopal Church, have four children and reside in Galveston.

HABITAT AND REPRODUCTIVE BIOLOGY OF ANGELWINGS, *PHOLAS ORIENTALIS* (GMELIN)

LIBERATO V. LAURETA AND EVELYN T. MARASIGAN
Institute of Aquaculture
College of Fisheries
University of the Phillipines in the Visayas
Miagao, Iloilo, Philippines 5023

ABSTRACT The angelwing, *Pholas orientalis* (Gmelin) is indigenous to the coastal waters of the Provinces of Negros Occidental, Capiz and Iloilo in Central Philippines. They burrow into either muddy sand substratum in the littoral zone or compact bluish-gray muddy sand in the sub-littoral zone. They burrow to a depth of over 0.3 m and once extracted can never return. Specimens studied were invariably dioecious without apparent sexual dimorphism. Sexual maturity is reached at a shell length of 59 mm and 64 mm for males and females respectively. Each sexually mature individual possesses a gonad that is imbedded in the ventral side of the viscera. Both male and female gonads are arborescent in form and have the same coloration. Samples collected from Barotac Nuevo, Iloilo showed that the peak of spawning occurred from June through October and gametogenesis started in October.

KEY WORDS: *Pholas orientalis*, angelwing, reproductive cycle, gonad, spawning

INTRODUCTION

The angelwing, *Pholas orientalis* Gmelin, is one of the species of the family Pholadidae found in the Philippines. The other species are: *Barnea dilatata*, *B. manillensis*, and *Martesia striata*. *Pholas orientalis* is edible and is marketed either fresh or dried in Hongkong (haw chung), Malaysia (siput selat batu), Thailand (hoy pim), and Philippines (diwal) (Ablan 1938; Davidson 1976; Saraya 1982; Young and Serna 1982; Tokrisana et. al. 1985; Amornjaruchit 1988). It has a sweet, juicy and tender taste, making it one of the most highly sought bivalves in Central Philippines. However, indiscriminate harvesting has resulted in the depletion of most of the natural beds.

To date, the study of Ablan (1938) contains the only available information on the ecology and utilization of this species. To rehabilitate the depleted *P. orientalis* beds, detailed ecological and biological information is required. According to Rosell (1979), any attempt to manage the resource in the absence of baseline information is an exercise in futility. Thus this study was conducted to describe habitat and reproductive biology of the species.

MATERIALS AND METHODS

Habitat Adaptation

The study sites were Barotac Nuevo, Iloilo (122°47′N and 10°55′E) along Guimaras Strait and Roxas City, Capiz (122°45′N and 11°37′E) adjoining Pilar Bay, both in Central Philippines (Fig. 1). Ecological data from five random stations in each area were monitored during the study period. The grain size characteristics of the bottom sediments were determined after the procedure described by Buchanan (1971). Water temperature was measured using a calibrated laboratory thermometer and salinity was monitored using a refractometer. The pH of the water was determined using a pH meter. Monitoring of the environmental parameters was conducted from May 1994 to August 1995 at the Barotac Nuevo site and August 1996 to July 1997 in the Roxas City area.

Determination of Reproductive Biology

The specimens (n = 6–20) used for the study on reproductive biology were collected every month (May 1994 to August 1995) from the waters of the Barotac Nuevo site. Specimens were brought to the laboratory, where the size lengths were measured using a caliper, then shucked, and the gonads dissected. A portion of the gonad was examined with a Nikon Optiphot microscope to determine the sexes. The stages of maturity and gametogenic cycles were determined from histological preparations. Permanent mounts of the gonads were prepared following the modified Bell and Lightner (1989) method. The description of the gonadal stages were made following developmental stages for other clams (Jones 1981; Nash et al. 1986; Hesselman et al. 1989; Shafee and Daoudi 1991; Ponurovsky and Yakovlev 1992).

RESULTS

Habitat Adaptation

The characteristics of the two natural beds of Pholas orientalis in Central Philippines are shown in Table 1. *P. orientalis* from Barotac Nuevo were found to burrow in compact muddy sand (particles < 0.25 mm) covered with a thin layer of silt in littoral areas. No specimens were found in the sandy substratum of the littoral zone and on the deeper water. Few mangrove trees were found in the area, and seagrasses and macrobenthic algae were not observed. At Roxas City area, the angelwings occurred in the sublittoral areas to a depth of 8 m during the highest high tide, the bed being bluish gray compact muddy sand (coarse silt). No *P. orientalis* were found in the sandy mud bottom of the littoral zone. The natural bed was wholly devoid of mangrove trees and any rooted plants. In both locations, the angelwings burrowed in the substrata to a depth of about 0.3 m. On some occasions, burrows were found almost adjoining and may have met and crossed one another.

The trends of physico-chemical parameters (temperature, salinity and pH) in the two study sites during the period of observation are shown in Figure 2. The ambient water temperature in Barotac Nuevo ranged from 28 °C to 30 °C, and did not fluctuate widely. The lowest recorded temperature readings were in the months of December through February. At the Roxas City site, wider fluctuations in water temperature were observed (24 °C to 31 °C) with December to February being the coldest months. At both sites, the salinity readings were between the range of 30–35 ppt. A pH range

Figure 1. The natural beds (▬) of *P. orientolis* in Central Philippines. (●) Barotac Nuevo study site, and (✱) Roxas City study site.

from 7.8 to 8.2 was recorded throughout the study period at both study areas.

Reproduction

Sex

Out of total 147 sexually matured specimens that were used in this study, no hermaphroditic individuals were observed. Angelwings were dioecious without apparent external dimorphism. Once sexual maturity was attained, the single gonad was fused or imbedded on the ventral side of the visceral mass, extending from the anterior to the posterior part. Ripe male and female gonads had a creamy coloration, and were arborescent in form (Fig. 3A), whereas spent gonads were yellowish and flaccid (Fig. 3B). The epithelial walls of the viscera also reflected an almost creamy coloration, causing difficulty in sex differentiation and determination of the size of the gonad and gonadal index. Of the same 147 total gonads that were dissected, 78 (53%) were males, and 69 (47%) females.

TABLE 1.

Ecological information on the two natural beds of *Pholas orientalis* in Central Philippines.

Study Site	Habitat Type	Maximum Water Depth (m)	Substrate Type	Vegetation
Barotac Nuevo	intertidal	>1	muddy sand (particles <0.25 mm)	mangrove
Roxas City	sublittoral	8	compact bluish gray muddy sand (particles <1.00 mm)	none

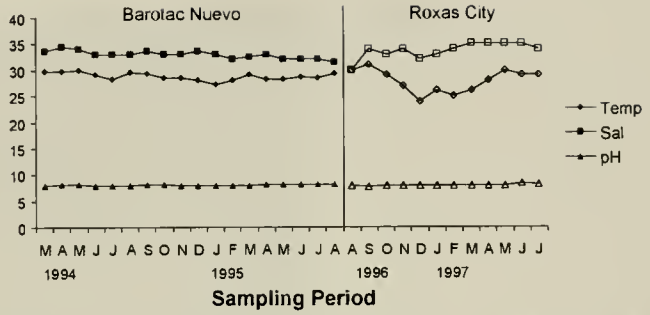

Figure 2. Some physico-chemical characteristics of water in the two natural beds of *P. orientalis* in Central Philippines.

Sexual Maturity

The specimens examined in this study ranged from 50–156 mm shell length. Most were found to be sexually mature. The minimum shell length of clams containing maturing gametes was 59

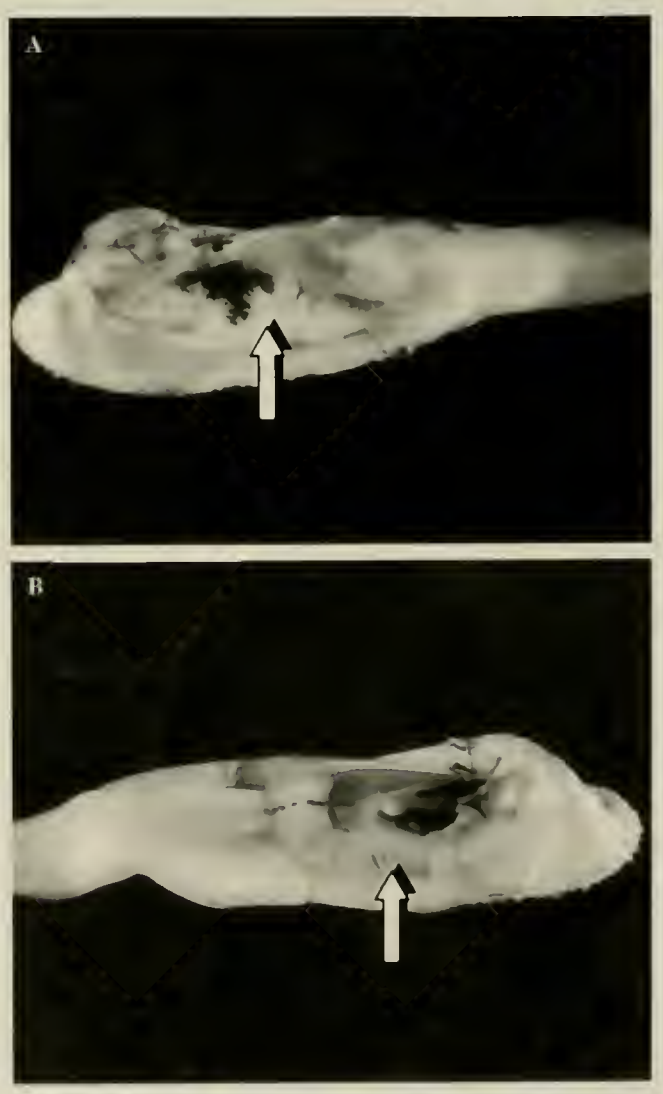

Figure 3. *P. orientalis* with (A) ripe gonad, and (B) spent gonad.

mm and 64 mm for males and females, respectively. The ages of the angelwings, however were not determined.

Gonadal Phase and Spawning

The gonadal state in both sexes was divided into five phases: early active, late active, ripe, partially spent and spent. The percentage occurrence of gonadal stages of male and female *P. orientalis* from Barotac Nuevo is shown in Fig. 4A and B, respectively.

Early active stage. Females follicles were empty and lined with small developing oocytes and oogonia. In males, few and loosely arranged spermatozoa were found in the center of the lumen of the follicle. These conditions occurred during the months of October to January. During this period, 14% of the male and 33% of the female angelwings population were in the early active phase.

Late active phase. In females, increased numbers of enlarging oocytes were freed in the lumen of the follicles. Oocytes were irregular in shape and had a wide range of sizes. In males, spermatocytes predominated the basal membrane of the follicle and numerous spermatids were found at the center of the follicle lumen. For both male and female gonads, about 17 to 60% were in the late active phase during the period December to May.

Ripe phase. In the female gonad rounded and ripe oocytes (with nucleus and nucleolus) were free in the lumen. In males, the gonad was predominated by mature spermatozoa in the lumen of the follicle; the acidophilic sperm tails formed lines radiating from the center of the follicle lumen. Specimens with ripe gonads were collected during the months of December to July. The percentage of ripe females ranged from 14.3 to 66.7, whereas males with ripe gonads ranged between 11.1 and 66.7.

Partially spent. Male gonads had spermatozoa missing in the central lumen of the follicle. Female gonads contained fewer ripe oocytes and appeared flaccid. Both types of gonad occurred in the months of May to October with percentage occurrence at 14.3 to 57.1.

Spent. Empty shrunken follicles were characteristic of spent gonads. This gonadal phase was observed from the months of June to October. By October, most of the angelwings had spawned.

DISCUSSION

P. orientalis is a commercially important yet poorly understood bivalve species found in Central Philippines. An early survey of Ablan (1938) showed that angelwings are indigenous to the coastal waters of Hinigaran, Pontevedra, Valladolid, and San Enrique in Negros Occidental, Philippines. A more recent survey indicated the presence of this species in the coastal waters of Barotac Nuevo toward San Dionisio in the Province of Iloilo and in Ivisan, Sapian, Panay, Pilar, Pontevedra and Roxas City all in the Province of Capiz (Fortes, unpublished). Apart from these areas no other site has been identified for the collection of the angelwings in the country. All the locations were within 3 to 100 miles at each other.

In this study, angelwings were found in either compact muddy sand or bluish gray muddy sand (with coarse silt) of the littoral or sublittoral zones. Ablan (1938) found the angelwings in a muddy

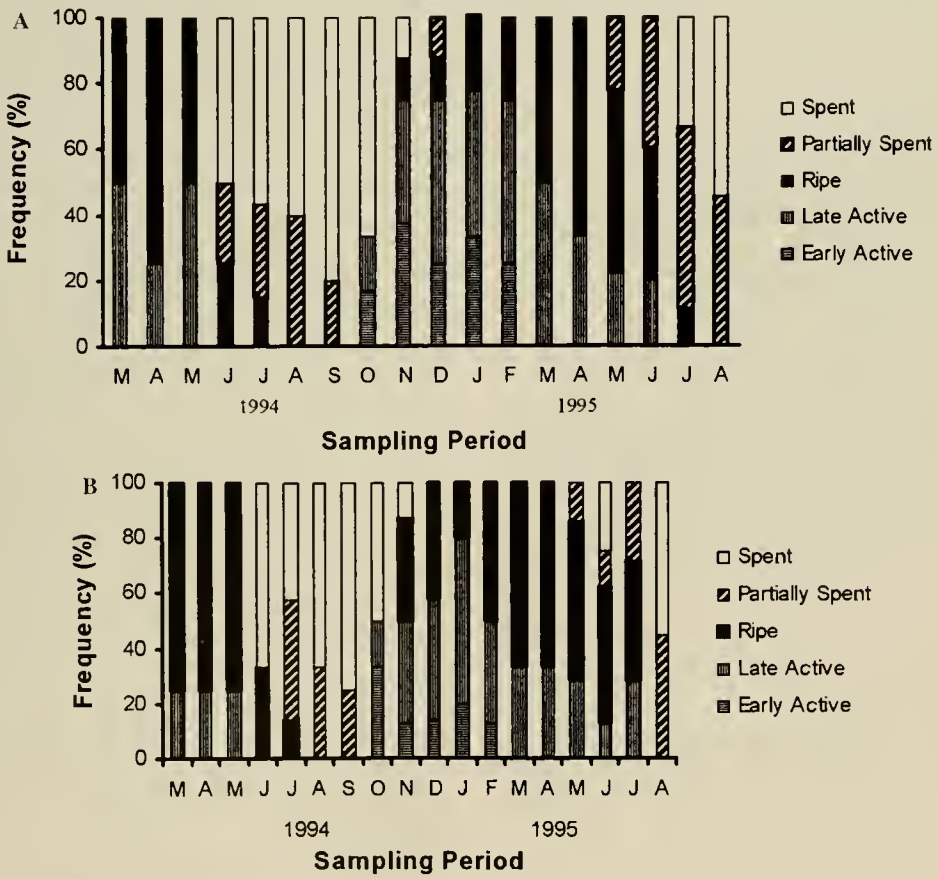

Figure 4. Reproductive cycle of *P. orientalis* in Barotac Nuevo, Central Philippines. Relative frequency of gonadal stages of (A) male, and (B) female between March 1994 to August 1995.

coastal land of Negros Occidental. A related species, *Cyrtopleura costata* has been observed to inhabit the sandy mud substratum in shallow waters from southern Massachusetts, USA, to Brazil (Turner 1954; Abbott 1974; Rios 1975). No clear explanation could be offered for the limited distribution of angelwings in the Philippines, and their contrasting ecological habitats (i.e., type of bottom sediments, water depth).

The pholads are capable of burrowing to a depth over 0.3 m (Ablan 1938; Allan 1959; this study). They live in the burrows for life (Allan 1959), and once extracted from their lodge they are unable to return. The burrowing ability is necessary to protect themselves from predators and the adverse effects of the physical environment as their shells are fragile. For *C. costata*, they begin burrowing after larval settlement, and recorded effective burrowing size was at a mean shell length of 11.7 mm (Gustafson et. al. 1991). Larger individuals (> 15 mm) of the same species were unable to rebury and had to be manually placed beneath the sediments during field-planting. However, effective burrowing size for the *P. orientalis* is not known yet.

Angelwings seem to have an extended annual breeding cycle, where initiation of gametogenesis begins almost after spawning. It was observed that sizes of specimens had no effect on the timing of gametogenesis. Small or large specimens, as long as they are sexually mature exhibited almost simultaneous gametogenesis. Gametogenesis was observed in the months of October to January. The month of October was period when most of the clams were partially spent or spent. The peak of spawning occurred in the months of June and October, at onset of the rainy season in the Philippines. Chanley and Andrews (1971) reported the spawning period from May through September for *C. costata* from Virginia, USA, whereas specimens from subtropical Florida were ripe in the summer months of June through August. The cyclical reproductive pattern observed in *P. orientalis*, however, cannot be definitely and clearly related to temporal changes in temperature and salinity. The lack of effect of temperature on the reproductive cycle was similarly observed on venerid clams like *Megapitaria aurantiaca, M. squalida*, and *Dosinia ponderosa* from Bahia Zihuatanejo, Mexico (Baqueiro and Stuardo 1977 cited by Garcia-Dominguez et al. 1998), and the giant reef clam *Periglypta multicostata* in Isla Espiritu Santo, Baja California Sur, Mexico (Garcia-Dominguez et al. 1998).

ACKNOWLEDGMENTS

We wish to thank the Fisheries Sector Program of the Department of Agriculture and the Sangguniang Panglungsod and the Mayor of the City Government of Roxas City, Philippines for funding this work. Special thanks are due also to the IA staff particularly to Ms. Janet O. Fernandez, Ms. Jane Apines and Ms. Shirley Miagao; and the fisheries staff of LGU-Roxas City, particularly Mrs. Belinda Garido, for their technical assistance. We sincerely thank Dr. Arnulfo Marasigan for improving the manuscript.

INFLUENCE OF DIET ON SURVIVAL, GROWTH, AND PHYSIOLOGICAL CONDITION OF FINGERNAIL CLAMS *MUSCULIUM TRANSVERSUM*

TERESA J. NAIMO,[1] W. GREGORY COPE,[2] EMY M. MONROE,[1] JERRY L. FARRIS,[3] AND CRISTIN D. MILAM[3]

[1]*U.S. Geological Survey, Upper Midwest Environmental Sciences Center, 2630 Fanta Reed Road, La Crosse, Wisconsin 54603*

[3]*Arkansas State University, Department of Biology, P.O. Box 599, State University, Arkansas 72467*

ABSTRACT The effects of diet and laboratory holding time on survival, growth, and physiological condition of fingernail clams *Musculium transversum* were evaluated in a 112-day study. The diets included a commercial oyster diet, a suspension of commercial rabbit pellets, a suspension of fine, organic-rich sediment, and a complete sediment renewal every 14 days. Sediment and clams were obtained from a relatively uncontaminated site in the Upper Mississippi River. The experimental design consisted of 18 370-mL beakers per diet, each containing 5 cm of surficial sediment and 15 clams. Survival of clams was measured daily in each unit. Three units from each diet were randomly removed on days 7, 14, 21, 28, 56, and 112, and clams were measured for shell length. Glycogen and cellulase activity were measured in composite samples (5 clams per sample) at each of the six time intervals. Cellulase activity did not vary among diets or with time. Survival, growth, and glycogen varied significantly among diets, and glycogen concentrations varied with time, regardless of diet. Clams exposed to the two sediment diets were 2.4 times more likely to survive than clams exposed to the commercial diets. Survival of clams in all diets exceeded 80% through day 21. Although clams maintained an acceptable survival rate for 21 days, their physiological condition was compromised much earlier, given that glycogen reserves were reduced by 14–54% after only 7 days. Thus, laboratory tests with fingernail clams should include physiological measures, in addition to survival, to ensure that clams are in suitable condition before and during testing.

KEY WORDS: Diet, *Musculium transversum*, survival, growth, biomarker

INTRODUCTION

Fingernail clams are an important component in the benthic invertebrate community of many large rivers and, in the Upper Mississippi River, have undergone periodic, pronounced declines in abundance in recent decades (Wilson et al. 1995). For example, densities in Pool 19 (near Keokuk, IA) averaged 32,000/m^2 in 1985 and progressively declined to 0 in 1990, and river-wide recovery has been slow. Toxicity of bulk sediment or pore water has been suggested as a factor contributing to the decline in fingernail clams in the river (Wilson et al. 1995). In particular, concentrations of un-ionized ammonia in sediment pore water from the Upper Mississippi River often exceed concentrations demonstrated to inhibit growth of fingernail clams in laboratory studies (Frazier et al. 1996). To assess these and other potential causes of the decline in abundance requires that clams be collected from the field, held in the laboratory, and tested through controlled experimentation. However, information on the relative condition of clams during long-term holding and its effect on the outcome of laboratory tests is lacking (Naimo et al. 2000).

The physiological condition of an organism is dependent upon its nutritional status (Lanno et al. 1989, Foster et al. 1993). Yet, the importance of nutrition as a factor modifying physiological condition has been largely overlooked. Data on how the condition of an organism responds to its nutritional status are critical for understanding the importance of diet as a variable in designing experimental studies with benthic organisms.

Recently, physiological indicators of condition such as glycogen concentration and cellulase activity have been used to assess the relative health of bivalve mollusks (Hemelraad et al. 1990, Haag et al. 1993, Farris et al. 1994, Naimo et al. 1998). Glycogen is the most readily available storage form of glucose in many animals, including freshwater mussels. As such, glycogen concentrations have been used successfully as an indicator of physiological condition in unionid mussels after exposure to contaminants (Hemelraad et al. 1990) and after infestation by zebra mussels (Haag et al. 1993). Similarly, cellulase activity is an indirect measure of feeding because it measures the rate of breakdown of complex sugars into simple molecules (Farris et al. 1988). Extensive use of cellulase activity in monitoring programs for molluscs has shown that responses at the biochemical level can be measured where pollutants or stress first exert their effect (Beeby 1993, Milam and Farris 1998). In these studies, the predictive capability of the enzyme assay has been compared with extensive testing of more traditional biological endpoints in toxicity assessments. Controlled laboratory and field exposures have provided evidence that reductions in enzyme activity are related to the eventual survival of the animal and to more subtle changes that occur in filtration, growth, and bioaccumulation rates (Farris et al. 1994, Milam and Farris 1998).

We examined survival, growth, and physiological condition in clams provided different food sources in a 112-day laboratory study. Our specific objective was to evaluate the effect of diet on the survival, growth, and physiological condition of fingernail

clams *Musculium transversum* (Say 1829). Furthermore, because we were interested in the transferability of these data to standardized tests with benthic invertebrates, we examined differences in survival, growth, and physiological condition between clams fed two commercially available diets (easily reproducible, but a non-indigenous diet) and two diets containing sediment (not as reproducible, but more indigenous).

MATERIALS AND METHODS

Experimental Design

We obtained about 600 fingernail clams with a Ponar dredge from Pool 13 of the Upper Mississippi River for use in the laboratory test. During collection, clams were placed in ice chests containing sediment and water from the river. The water in the ice chests was aerated and its dissolved oxygen content was measured at 30-min intervals to maintain concentrations above 60% of saturation. To obtain an estimate of the physiological condition of clams at this point in time, we obtained an additional 15 clams, placed them on dry ice in the field, and stored them at −84 °C in the laboratory before analysis of glycogen concentration and cellulase activity.

The uppermost 5 cm of sediment from a single sampling site in Pool 7 of the Upper Mississippi River (Lake Onalaska, river mile 704.5) that contained an abundant fingernail clam population was obtained with a van Veen dredge. Sediment was placed into 4-L glass jars, held on ice, transported to the laboratory, and stored in a refrigerator for no more than 5 days before the start of the test. Three subsamples of homogenized sediment (each 20–25 g wet weight) were analyzed to describe textural composition (Guy 1969, Plumb 1981) and volatile matter content (American Public Health Association et al. 1992). Sediments averaged (mean ± 1 standard error [SE]) 4 ± 0.2% sand, 54 ± 2.4% silt, 42 ± 1.8% clay, and 7.8 ± 0.9% volatile matter.

The experimental unit was a 370-mL beaker. All experimental units were placed into one of two 900-L water baths (3 m length × 0.8 m width × 0.4 m height). Each water bath was partitioned lengthwise with Plexiglas to provide four compartments, one for each diet. Eighteen experimental units were randomly allocated into each compartment. A temperature of 17 ± 2 °C was maintained with submersible quartz heaters. About 24 h before the addition of clams, 184–188 g of surficial sediment (about 4–5 cm) and 200 mL of well water from the Upper Midwest Environmental Sciences Center were added to each experimental unit. On day 0, we randomly allocated 15 clams, each measuring 4–6 mm in shell length, into each experimental unit.

We measured the temperature, pH, and dissolved oxygen of the overlying water every Monday, Wednesday, and Friday in five randomly selected experimental units in each diet. Because fingernail clams are particularly sensitive to un-ionized ammonia (Hickey and Vickers 1994), we measured concentrations of total and un-ionized ammonia in three randomly selected experimental units every 14 days (Frazier et al. 1996). On days 7, 14, 21, 28, 56, and 112, clams from three randomly selected experimental units from each diet were sieved from test sediments, counted, recorded as dead or alive, measured for shell length to the nearest 0.1 mm, and stored at −84°C for later analysis of glycogen concentrations and cellulase activity. Glycogen concentrations (Naimo et al. 1998) and cellulase activity (Farris et al. 1988) were measured on composite samples containing five individuals from each experimental unit. Glycogen concentrations were reported as mg/g wet weight, and cellulase activity was expressed as a product (exocellulase activity times endocellulase activity in [units/g dry weight]^2). One unit of the enzyme is defined as the amount of enzyme required to liberate 1 mg of reducing sugar equivalent to that of glucose per hour with carboxymethylcellulose as a substrate.

Diet and Ration

Clams were fed one of four diets daily; two were commercially available diets, and two were formulated with sediments from the Upper Mississippi River (sediment diets). The commercial diets included an oyster diet, which was a mixture of two marine diatoms (50% *Thalassiosira pseudoana* and 50% *Skeletonema sp.*) fed at a rate of about 7μL/clam/day (8–10 × 10^9 cells/mL; Pacific Oyster Diet B, Coast Seafood Company, Quilcene, WA). The second commercial diet was a suspension of Kaytee® rabbit feed, with pellets made largely from alfalfa, fed at a rate of 2.5 mg/clam/day. The two sediment diets contained organic-rich sediments from relatively uncontaminated areas in the river and were the same sediment used as the substrate in all experimental units. One was a suspension of fine sediment fed at a rate of 2.5 mg/clam/day, and the other was a complete sediment renewal every 14 days.

The oyster diet, rabbit pellet diet, and suspended sediment diet were prepared about 2 days before the start of the experiment. The oyster diet comes in liquid form and was kept refrigerated. The rabbit pellet and the suspended sediment diets were prepared by blending 38 g of rabbit pellets or sediment with 400 mL of well water in a commercial blender for 5 min. The contents of the blender were transferred into a 1,000-mL volumetric flask and filled to the meniscus with well water. This process was repeated until we obtained 32 140-mL bottles of each diet. Once a week, one bottle of food for each diet was removed from a −20°C freezer and placed into a refrigerator; the quantity of food in each bottle was sufficient to feed all clams receiving those diets for 1 wk. Clams in the sediment-renewal diet were sieved from test sediments every 14 days, and another aliquot of sediment was replaced into each experimental unit. Sediments for this diet were the same sediments that were obtained at the start of the test, stored in a refrigerator until needed.

Statistical Analyses

Survival of clams was assessed by daily counts of dead shells on the sediment surface. In addition, at the six time intervals in which clams from three beakers were removed for physiological measurements, we also made direct mortality estimates; these data allowed us to check the accuracy of the daily mortality counts. Because these two estimates agreed more than 90% of the time, analyses of survival rate were performed on daily survival counts. We used the Cox proportional hazards model to determine whether survival rates of clams varied among diets (Cox 1972). To test for differences in survival between the commercial and sediment diets, we used the Wald test of equality (Parmar and Machin 1995).

We analyzed growth, glycogen concentrations, and cellulase activity with analysis of covariance (ANCOVA), with time in the laboratory as the covariate. Because most clams did not survive after day 56, statistical analyses were only conducted until day 56. Orthogonal contrasts were used to compare differences in growth and physiological condition between the commercial and sediment diets when the ANCOVA was significant. We did not record the shell length of each clam on day 0; instead, we ensured that all

clams ranged from 4 to 6 mm in length. Because shell length did not differ among diets at day 7 ($P = 0.21$), subsequent analyses were performed on shell length measures from day 7 through day 56. A type I error α of 0.05 was used to reject all null hypotheses.

RESULTS

The quality of the overlying test water was similar among diets (Fig. 1). For example, grand means (averaged over all diets and time periods) ranged from 15.4°C to 15.7°C for temperature, 8.2 to 8.3 for pH, and 9.7 to 9.8 mg/L for dissolved oxygen. Concentrations of total (range, 0.03–0.13 mg/L) and un-ionized (0.002–0.008 mg/L) ammonia were well below concentrations that adversely affect fingernail clams in laboratory exposures (Sparks and Sandusky 1981).

The survival rate of fingernail clams varied significantly among diets ($P = 0.0001$). Survival rates were lowest in clams fed the oyster diet, whereas survival was highest in clams receiving the sediment-renewal treatment (Fig. 2). For example, survival averaged 44% in the oyster diet, 66% in the rabbit-pellet diet, 73% in the suspended-sediment diet, and 84% in the sediment-renewal diet at day 56. By day 112, only 6% of the clams in the sediment-renewal treatment were alive, and none survived in the other three dietary treatments.

Survival was significantly greater in clams provided the sediment diets, relative to the commercial diets ($P = 0.0001$). After 56 days in the laboratory, for example, survival of clams fed the sediment diets averaged 79%, whereas survival averaged 55% in clams fed the commercial diets. However, there was little difference in survival of clams among diets early in the test; survival of clams in all diets exceeded 80% through 21 days of exposure. A unique feature of the proportional hazards model is the ability to calculate a risk ratio, or the estimated hazard of surviving in one diet versus another. For example, clams provided the oyster diet were 1.9 times more likely to die than clams fed rabbit pellets (Table 1). Additionally, clams fed the oyster diet were almost 5 times more likely to die than clams in the sediment-renewal treatment. Furthermore, clams fed the commercial diets were 2.4 times more likely to die than clams fed the two sediment diets.

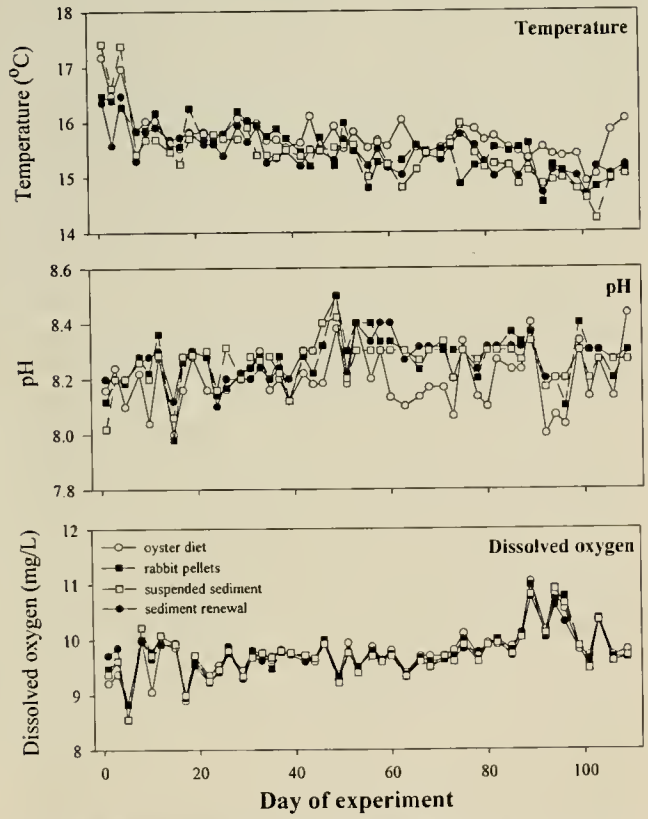

Figure 1. Mean temperature, pH, and dissolved oxygen in overlying test water from five randomly selected experimental units containing fingernail clams *Musculium transversum* fed one of four diets daily for 112 days.

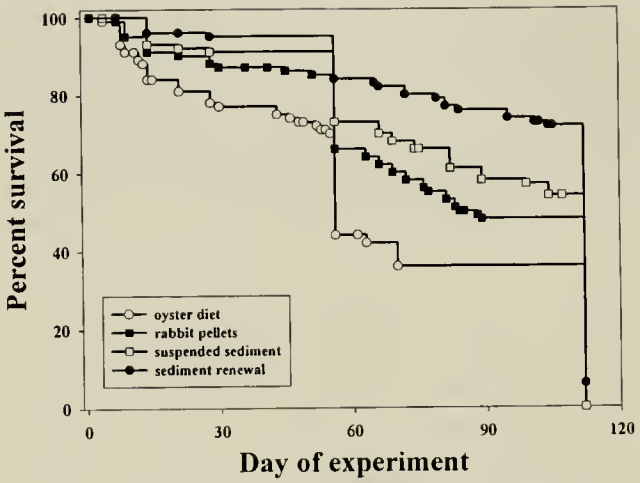

Figure 2. Survival of fingernail clams *Musculium transversum* fed one of four diets in a 112-day laboratory test.

The shell length of fingernail clams also varied significantly among diets ($P = 0.02$). Clams receiving the sediment-renewal treatment were significantly larger than clams in the other three dietary treatments. For example, clams in the sediment-renewal

TABLE 1.

Estimated probability values, risk ratios, and upper and lower 95% confidence limits from the survival rate analysis in fingernail clams fed four different diets in a 112-day laboratory experiment.

Contrast	*P* Value	Risk Ratio	Lower 95% Confidence Limit	Upper 95% Confidence Limit
Oyster diet, suspended sediment	0.0001	2.6	1.9	3.5
Rabbit pellets, suspended sediment	0.1124	1.3	0.9	1.9
Sediment renewal, suspended sediment	0.0120	0.5	0.3	0.9
Oyster diet, rabbit pellets	0.0001	1.9	1.9	2.0
Oyster diet, sediment renewal	0.0001	4.8	4.0	5.8
Rabbit pellets, sediment renewal	0.0002	2.4	2.2	2.8
Commercial diets, sediment diets	0.0001	2.4	1.9	3.2

The risk ratio is the estimated hazard of surviving in one diet *versus* another diet; for example, clams fed the oyster diet were 2.6 times more likely to die than clams fed the suspended-sediment diet.

treatment averaged 4.8 mm in length over the 56-day duration, whereas clams in the other three dietary treatments ranged from 4.3 to 4.4 mm. Furthermore, the size of clams did not differ between clams provided the commercial and sediment diets (P = 0.50), nor did shell length vary with time in the laboratory (P = 0.23; Fig. 3a). At day 7, clams ranged in length from 4.2 to 4.8 mm and at day 56, they ranged in length from 4.5 to 4.8 mm.

Glycogen concentrations in clams varied significantly among diets (P = 0.049; Fig. 3b). In particular, glycogen concentrations differed between the commercial and sediment diets (P = 0.02). For example, mean glycogen concentration was 3.5 mg/g in clams fed the oyster diet and 4.1 mg/g in clams fed the rabbit pellets. In contrast, glycogen concentrations averaged 2.8 mg/g in the suspended-sediment diet and 3.0 mg/g in the sediment-renewal treatment. However, glycogen concentrations declined significantly with time in the laboratory, regardless of diet (P = 0.0001). For example, glycogen concentrations in clams in the sediment-renewal treatment averaged 4.6 mg/g at day 7 and had declined to only 2.2 mg/g by day 56. Moreover, because there was no diet*time interaction (P = 0.49), the response of glycogen with time was similar among diets. For reference, glycogen concentrations averaged 5.4 ± 0.5 (SE) mg/g in clams when they were removed from the Mississippi River.

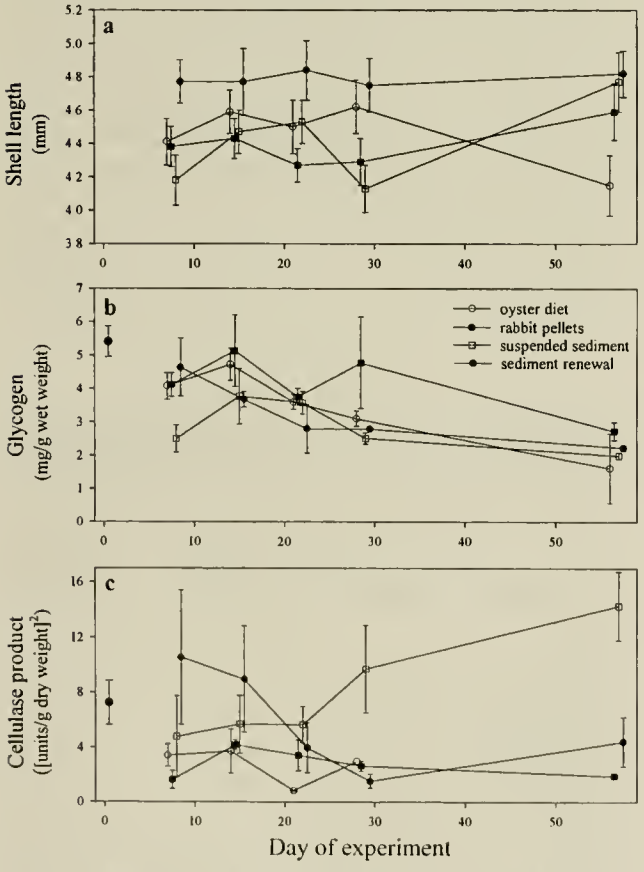

Figure 3. Mean (a) growth, (b) glycogen concentrations, and (c) cellulase activity in fingernail clams *Musculium transversum* fed one of four diets in a 112-day laboratory test. Glycogen (mg/g wet weight) and cellulase activity ([units/g dry weight]²) were measured on a composite of five clams from each of three experimental units sampled on days 7, 14, 21, 28, and 56. Data point at day 0 is the mean (±1 SE) glycogen and cellulase in clams at the time they were collected from the Upper Mississippi River.

In contrast, cellulase activity did not vary among diets (P = 0.12) nor with time held in the laboratory (P = 0.32; Fig. 3c). Cellulase activity, averaged over the 56-day exposure, ranged from 0.8 to 5.3 (units/g dry weight²) in the oyster diet, 0.8 to 4.8 in the rabbit pellets, 1.1 to 14.7 in the suspended sediment, and 0.6 to 19.8 in the sediment renewal. Likewise, cellulase activity remained similar throughout exposure (averaged over all diets) and ranged from 1.6 to 10.5 at day 7 and from 1.8 to 14.3 at day 56. The lack of significant diet or time effects was presumably due to the large variance in cellulase activity among replicates. The coefficient of variation (CV) usually averaged well over 50%, likely obscuring any diet or time effects. For reference, cellulase activity averaged 7.3 ± 1.6 (SE) in clams when collected from the Mississippi River.

DISCUSSION

Survival of fingernail clams was greater in treatments containing sediment from the Upper Mississippi River than in treatments with commercial diets. A similar observation was made by Gatenby et al. (1996) with juvenile *Villosa iris*. In a 45-day laboratory experiment, juvenile mussels reared on sediment and algae had significantly higher survival (67%) than juveniles reared without sediment and fed only algae (22%). Although several investigators have observed higher survival rates in molluscs in experiments with sediment, relative to no sediment (Gatenby et al. 1996, Naimo et al. 2000, present study), the mechanism(s) contributing to this are largely unknown. It has been hypothesized that the addition of a food source, along with fine sediments and their associated resident bacteria, may enhance digestion in molluscs (Crosby et al. 1990, Naimo et al. 2000). However, the addition of bacteria common to riverine systems did not improve survival or enhance growth in laboratory studies with juvenile *Villosa iris* (Gatenby et al. 1996). Naimo et al. (2000) hypothesized that physical contact with sediment may enhance the survival of fingernail clams relative to exposures without direct sediment contact. They observed that *Musculium transversum* were twice as likely to survive when provided with direct sediment contact, suggesting that clams received nutritional benefit from sediment contact by feeding directly on indigenous, sediment-associated food sources.

Although survival of fingernail clams differed substantially among diets after 112 days, survival exceeded 80% through day 21 in all diets. In standardized toxicity tests with benthic invertebrates, 21–28 days is a standard test duration (American Society for Testing and Materials 1992), and tests are generally considered unacceptable if survival of control animals is less than 80%. Thus, in short-term standardized tests with fingernail clams, excessive mortality in control organisms would not invalidate test results.

Growth of fingernail clams in the laboratory was minimal over the 56-day duration. Clams in the sediment renewal treatment seemed to maintain their size, whereas shell growth in clams in the other diets was variable. Differences in shell growth in the sediment-renewal treatment, relative to the other diets, may be related to the volume of available food (i.e., sediment). Clams in the sediment renewal treatment received about 736 g of sediment over 56 days, whereas clams in the suspended-sediment and rabbit-pellet treatments received only 2.1 g of food over this duration. Although food quality as well as quantity are important, the magnitude of the difference in quantity may have contributed to differences in growth among diets. In addition, the magnitude of shell growth observed in our study (0.1–0.6 mm over 56 days) was sufficiently small such that variation in measurement of shell

length could be a major source of variation and uncertainty in this analysis. Thus, future studies should measure individually marked organisms and should use techniques appropriate for detecting small changes in size. The lack of shell growth in this experiment was not unexpected. For example, Gale (1977) observed that *Sphaerium transversum* maintained in the laboratory in chambers containing silt from the Mississippi River grew slowly, with a mean length increase of 1.3 mm after 33 days.

Glycogen concentrations have been used extensively in bivalves as an indicator of physiological health (Haag et al. 1993, Naimo et al. 1998); however, it is unclear how much glycogen is required for maintenance, growth, and reproduction. In the present experiment, we documented significant differences in glycogen concentrations among diets, particularly between the commercial diets and the sediment diets. However, the pattern in glycogen concentrations was such that glycogen was elevated in clams fed the commercial diets, relative to the sediment diets, in contrast to the patterns in survival. Two alternate hypotheses for the reduction in glycogen in the sediment diets include (1) clams were getting enough nourishment from the sediment for maintenance metabolism but were unable to store glycogen and (2) clams were not getting enough nourishment from the sediment and were catabolizing carbohydrate stores. Whichever the case, glycogen concentrations declined with time in all dietary treatments, suggesting that health was declining over this time period. Glycogen concentrations declined by 14–54% by day 7 and 50–70% by day 56, relative to concentrations in clams when they were taken from the river.

Some researchers have suggested that the benefit of addition of sediment to juvenile bivalve cultures is to provide resident bacteria to enhance enzymatic activity (Crosby et al. 1990). However, we did not observe any enhancement in cellulase activity between clams maintained in sediment and clams fed commercial diets. Cellulase activity in clams was highly variable (mean CV = 67%), making detection of dietary effects at an acceptable statistical level difficult. To our knowledge, measurement of cellulase activity has not been previously performed on fingernail clams; thus, further refinement of methods could reduce variation associated with this measure.

In conclusion, we observed significant differences in survival, shell growth, and glycogen concentrations of fingernail clams fed different diets, implying that some diets were better than others. However, the general negative slope of most response variables (survival, shell growth, and glycogen) suggests that clams were declining in health with time in the laboratory, regardless of diet. Therefore, a better diet is needed to maintain clams in a healthy state in the laboratory. Although clams maintained an acceptable survival rate for 21 days in the laboratory, their physiological condition was compromised much earlier. Thus, valid short-term toxicity tests with fingernail clams can be conducted in the laboratory, but their ability to predict toxicity to field populations is uncertain. Therefore, laboratory tests with clams should include a physiological measure, such as glycogen, in addition to survival to ensure that clams are in suitable condition before and during testing in laboratory studies.

ABSTRACT We used allozyme electrophoresis to compare the genetic variation of an introduced and strongly isolated population of the edible clam *Tapes decussatus* in the Azores (Lagoa de Santo Cristo, São Jorge) with populations from the main range of the species (Ria and Thau). Observed and expected heterozygosity values, number of polymorphic loci, and mean number of alleles per locus in the main-range populations fall within the limits reported for *T. decussatus* and other Venerid clams. In contrast to previous studies on Venerid clams, we observed no heterozygote deficiencies. In the introduced Lagoa population, we observed a strong reduction of allelic diversity and expected heterozygosities and an effective population size of only 5.30. The Lagoa population is only slightly differentiated from populations from the species' main range and may thus be of low "biological value." Exploitation of *T. decussatus* could therefore be allowed to continue but must follow strict collection guidelines, especially given that only 15% of the area is suitable for exploitation. Otherwise, a unique component of the Azorean fauna that also serves as a fishery resource may be lost.

KEY WORDS: Azores, allozymes, founder effect, *Tapes decussatus*, population genetics, conservation

INTRODUCTION

Small or isolated populations can contribute substantially to biodiversity, and the conservation of such populations must be an important part of any effective Biodiversity Action Plan (Usher 1997). The genetic effects in small populations are manifold (Harris 1984, Usher 1987). Small effective population sizes (N_e) often show a loss of genetic variability (i.e., founder effects, bottlenecks) caused by genetic drift (Lacy 1987). Apart from losing (rare) alleles, small populations often lose common alleles by chance (Nei et al. 1975, Simberloff 1988) and may show elevated inbreeding, which may impair reproductive fitness. In addition, the loss of genetic variability may limit the ability of a population to adapt to changing environments (Frankel and Soulé 1981, Thorpe et al. 1995). Over the long term, these effects may enhance the risk of extinction (Soulé 1987). Effective conservation or management plans require a thorough knowledge of the genetic population structure before adequate measures can be taken. In this study, we estimated the effective population size and investigated whether genetic variation is reduced in an introduced, isolated population of the commercial edible clam *Tapes decussatus* (Linnaeus, 1758).

The main range of *T. decussatus* extends from Great Britain in the north to Senegal in the south, along the Iberian peninsula, and into the Mediterranean to the east (Tebble 1966). Outside its main range, the species has been introduced in the Lagoa de Santo Cristo, a small and isolated lagoon situated at the north coast of the island of São Jorge in the Azores, approximately 1,400 km from the African/European coasts, where it was discovered for the first time in 1967 (Morton 1967). This lagoon has a total area of 0.86 km^2 (length, 500 m; width, 250 m; and maximum depth, 6 m) and harbors a unique fauna (Morton 1967, Santos 1985, Santos and Martins 1986, Morton and Tristão da Cunha 1993, Morton et al. 1998). The lagoon was classified as a Natural Partial Reserve in 1984 on the basis of its unique origin, geology, and the presence of the edible clam *T. decussatus*. In 1989, it was also declared a Special Ecological Area, to safeguard the unique breeding population of *T. decussatus* and to maintain the ecological equilibrium

*Corresponding author.

of the area. Although there is no written record, *T. decussatus* was probably introduced in the lagoon by humans, especially since the species occurs nowhere else in the Azores (Morton 1967, Morton and Tristão da Cunha 1993). Moreover, the planktonic stage of the larvae lasts approximately 10 days, during which larvae are transported by sea currents over a distance of 10–100 km (Borsa et al. 1991). Larval transport from the main range to the Azores by sea currents seems therefore unlikely.

At this moment, *T. decussatus* is the main commercially exploited species of the lagoon (Fonseca et al. 1995). Santos and Martins (1987), Santos et al. (1989), and Gonçalves and Martins (1991) showed that the population of *T. decussatus* in the Lagoa de Santo Cristo was declining through overexploitation, especially in the intertidal parts of the lagoon, where clam collection is easy. The intense fishery resulted in smaller individuals in the intertidal area. These potential detrimental impacts on the clams and other species of the lagoon have obliged the Azorean government to establish a management program for the Lagoa de Santo Cristo. Therefore, the clam fishery at the lagoon is nowadays closed during a period that largely coincides with the breeding season of the species (May 15 to August 15; Santos and Martins 1987, 1991). The present research was performed to provide genetic data that may be relevant for further substantial management of the clam population.

MATERIALS AND METHODS

Four samples of *T. decussatus* were collected from three sites: Lagoa de Santo Cristo (SC; July 1992 and June 1993), Étang de Thau (Thau; French Mediterranean coast; August 1993), and Playa do Testal (Ria; Ria de Muros y Noya, Galicia, Spain; December 1993). Specimens were immediately frozen in liquid nitrogen for transport to the laboratory, where they were stored at −80 °C.

Forty specimens of each sample were surveyed for allozyme variation with vertical polyacrylamide gel electrophoresis (PAGE). Individual tissue homogenates were prepared by dissecting specimens in ice-cold distilled water and removing the digestive gland, the gills, the foot muscle, and the adductor muscles. Each of the tissues was separately weighted and homogenized in a 20% (w/v) aqueous sucrose solution (5 μL sucrose solution per mg tissue). Crude homogenates were centrifuged for 45 min at ±27,000 *g* at 5 °C to obtain clear supernatants for electrophoresis.

PAGE was performed as described by Backeljau (1987, 1989). Two electrophoretic buffer systems were used: (1) Tris/glycine pH 9.0 in the tray and Tris/HCl pH 9.0 in the gels and (2) Tris/citric acid pH 8.0 in both the tray and the gels. Enzyme staining recipes were adapted from Harris and Hopkinson (1976).

Twenty-six enzyme systems were screened in the four tissues (see Backeljau et al. 1994). Seven of these enzymes yielded interpretable genetic polymorphisms and were retained for further analysis (Table 1).

Alleles were designated alphabetically according to decreasing electrophoretic mobilities (A = most anodal = fastest-migrating allele). Previously typed specimens were included with each run to compare different gels. The BIOSYS-1 version 1.7 package (Swofford and Selander 1981) was used for estimating allele frequencies, mean numbers of alleles per locus (MNA), observed heterozygosities (H_o, direct count) and Nei's (1978) unbiased expected heterozygosities (H_e). Numbers of polymorphic loci (P) were simply counted. Weir and Cockerham's (1984) fixation indices (F_{is}) were estimated with GENEPOP version 3.0 (Raymond and Rousset 1995), and genotype frequencies were evaluated for departures from Hardy-Weinberg (HW) equilibrium expectations with the probability test implemented by the same program. The significance of F_{is} values was tested with FSTAT version 1.2 (Goudet 1995). Linkage disequilibria (LD) between loci were tested with the exact probability test in GENEPOP version 3.0. Whenever needed, testing procedures were corrected for multiple testing with the sequential Bonferroni method (Rice 1989). Nei's (1978) unbiased genetic distance between populations was calculated with BIOSYS-1 version 1.7.

The effective population size (N_e) of the population from the Lagoa was estimated in two different ways. One method estimates N_e from the changes in expected heterozygosity. In a population of size N_e, the initial heterozygosity (H_o) will decrease to H_t after t generations. The relationship between H_o and H_t is given by the equation $H_t = H_o(1 - 1/2N_e)^t$ (Crow and Kimura 1970). A second method (i.e., the temporal method) estimates N_e from temporal changes of gene frequencies as described by Waples (1989) and Hedgecock et al. (1992). Although a few *T. decussatus* individuals may spawn in their first year (Vilela 1950), the vast majority of individuals reach their sexual maturity at the beginning of their second year (Gallois 1977). Therefore, we used a generation time of 1 y for *T. decussatus*. An assumption of both methods is that the allozyme polymorphisms studied are selectively neutral. To test this, we performed the Ewens-Watterson test using the algorithm given in Manly (1985) and implemented by the program POPGENE version 1.31 (updated version of POPGENE version 1.2 of Yeh and Boyle [1997]).

Because many bivalves show a positive correlation between

TABLE 1.

Enzymes studied, E.C. numbers, enzyme codes, the tissue from which the enzyme was extracted, and the buffer system (TC = Tris/citric acid; TG = Tris/glycine) used to examine genetic variation in four *T. decussatus* populations.

Enzyme	EC Number	Code	Tissue	Buffer
Malate dehydrogenase	1.1.1.37	*Mdh*	Adductor muscle	TC
D-Octopine dehydrogenase	1.5.1.11	*Opdh*	Adductor muscle	TC
Isocitrate dehydrogenase ($NADP^+$)	1.1.1.42	*Idhp*	Digestive gland	TC
Phosphogluconate dehydrogenase	1.1.1.44	*Pgdh*	Digestive gland	TC
3-Hydroxybutyrate dehydrogenase	1.1.1.30	*Hbdh*	Digestive gland	TG
Leucylalanine peptidase	3.4.13.11	*Pep*	Gills	TG
Phosphoglucomutase	5.4.2.2	*Pgm*	Adductor muscle	TG

shell size and individual heterozygosity (e.g., Zouros and Foltz 1984), we checked for such a relationship to avoid the possibility that discrepancies in H_o values would merely reflect size differences between populations. Therefore, Pearson's product-moment correlation was calculated between shell length and numbers of heterozygous loci, as outlined by Diehl and Koehn (1985) and Fevolden (1992).

RESULTS

Pep revealed two independent banding zones, the cathodal of which was clearly polymorphic in the Thau and Ria populations, but monomorphic in the Lagoa population. Yet, because the bands in this zone were often confused, they were not used for genotypic analysis. The six remaining enzymes yielded information for seven putative loci (Table 1), the population genetic data of which are provided in Tables 2 and 3. Out of 18 HW tests, only 2 were significant (*Pgm* in Thau and *Idhp* in Ria; Table 2), but this was no longer so after sequential Bonferroni correction. Not surprisingly, F_{is} values taken over all loci in all populations were not significantly different from 0 ($0.193 < P < 0.27$). However, compared with the Lagoa population, the Thau and Ria populations had higher heterozygosity levels and nearly twice as many polymorphic loci and mean numbers of alleles per locus (Table 2). Only two of the 31 LD tests were significant (data not shown), but both cases were no longer significant after sequential Bonferroni correction. Nei's (1978) unbiased genetic distance between the samples ranged from 0.036 (between two samples from the Azores) to 0.23 (between Thau and two samples from the Azores) (Table 3).

The estimate of N_e with the temporal method was infinity. This result is probably an artifact caused by the small number of loci analyzed ($n = 3$) (Table 2). It simply indicates that the change in allozyme frequencies observed between the 2 years was not large enough to be distinguished from sampling error. The estimate of N_e obtained from the reduction of heterozygosity was 5.30. The test for neutrality gave nonsignificant results.

We found no significant correlation between individual heterozygosity and shell length (Thau, $r = 0.173$, $P = 0.733$; Ria, $r = 0.36$, $P = 0.556$; and Lagoa (pooled samples), $r = 0.48$, $P = 0.409$).

DISCUSSION

Observed and expected heterozygosity values, number of polymorphic loci, and mean number of alleles per locus in the Ria and Thau populations fall within the limits reported for *T. decussatus* and the palourde *Ruditapes philippinarum* (Table 4). As in many other bivalve species, heterozygote deficiencies have often been reported in *T. decussatus* and *R. philippinarum* (see references in Table 4), but at present the causes of this remain unclear (Zouros et al. 1988). Yet, in our study, we observed no heterozygote deficiencies. Nevertheless, our population genetic data of the Thau population are very similar to the results obtained by Jarne et al. (1988), Borsa and Thiriot-Quiévreux (1990), and Borsa et al. (1994) for the same population and for the nearby population of Étang du Prévost (Worms and Pasteur 1982). Moreover, genetic distances between our populations are similar to those reported by Jarne et al. (1988) (compare our Table 3 with their Table 4).

However, in the Lagoa population of *T. decussatus* in the Azores, we observed a strong reduction of allelic diversity and expected heterozygosities, but not heterozygote deficiencies, compared with main-range populations. Substantial losses of genetic diversity have also been observed in bivalves for which hatchery stocks have been established from only a few individuals (e.g., the oysters *Crassostrea gigas* [Gosling 1982, Hedgecock and Sly 1990] and *C. virginica* [Vrijenhoek et al. 1990, Gaffney et al. 1992]). This may have important implications when management and exploitation practices are developed. Many hatchery stocks or introduced populations have a low N_e value despite densities that can be very high (e.g., Saavedra 1997 and references therein). In the Lagoa, population densities of *T. decussatus* may reach 400 individuals/m^2 (Gonçalves and Martins 1991). Yet we estimated an effective population size of only 5.30 individuals. Founder effects, genetic drift, intentional selection, and inadvertent selection during culture are likely to reduce the genetic diversity of the Lagoa population further. The introduction of a small number of individuals a few decades ago probably resulted in the loss of genetic variation via founder effects. The strong isolation of this population probably does not allow transport of larvae from nearby populations (see Introduction), and genetic drift and inbreeding may further reduce genetic variability. These effects are probably reinforced by human activities such as selection during harvesting (e.g., the collection of only large adults). Indeed, the exploitation of *T. decussatus* in the Lagoa follows a classic "fishery" picture with old (i.e., large) shells lacking among empty shells in the lagoon because they were collected for consumption when alive (Morton and Tristão da Cunha 1993). It is unclear whether such selective harvesting affects the genetic structure of the population, because there was no association between individual heterozygosity and size. Yet this topic deserves further study, as Borsa et al. (1994) and Passamonti et al. (1997) found a high level of intrapopulation structuring, probably related to year-cohort heterogeneities, that perhaps indicate short-term selection or genetic drift (Borsa et al. 1994). Thus, harvesting a single age cohort (i.e., oldest and largest individuals) could affect the genetic population structure.

In none of the populations did we observe a significant correlation between shell size and individual heterozygosity. Some other studies also failed to show a relationship between individual heterozygosity and morphological traits such as size and growth (Adamkewicz et al. 1984, Volckaert and Zouros 1989, Gaffney 1990, Slattery et al. 1991), but others report negative (Wilkins 1978) or positive (Garton et al. 1984, Koehn and Gaffney 1984, Zouros and Foltz 1984, Gaffney 1990) associations, although associations may differ among populations (Gaffney 1990).

A positive relation between heterozygosity, body size, and survival was found in a population of *T. decussatus* that survived natural anoxic stress (Borsa et al. 1992). However, in other populations of the same species, Jarne et al. (1988) observed no association between asymmetry of left and right valves (as a measure of fitness, i.e., the more asymmetric the less fit) and heterozygosity, and an increased variance for morphological traits in the classes with low heterozygosity. This also appears to be the case for some of the *R. philippinarum* populations in the Po river lagoon in Italy (Fava et al. 1994). In that study, individual heterozygosity and phenotypic variability appeared to be negatively correlated, but the relationship was heterogeneous between populations (Fava et al. 1994).

Our allozyme data indicate that the Lagoa population from the Azores is genetically depauperate and only slightly differentiated from populations from the main range and may thus be of low "biological value" (i.e., in terms of biodiversity). Gathering of *T. decussatus* could therefore be allowed to continue. Nevertheless, given the lower genetic diversity of *T. decussatus* in the Lagoa, the low effective population size, and the depauperate intertidal region (Santos et al. 1985, Santos and Martins 1987), exploitation of this species must follow strict collection guidelines (see also Santos 1989), especially given that only 15% of the area is suitable for exploitation (Morton and Tristão de Cunha 1993). Otherwise, a unique component of the Azorean fauna that also serves as a small fishery resource may be lost. In addition, there is much to compare between Ilhéu de Vila Franca on the island of São Miguel in the Azores and the Lagoa de Santo Cristo. The faunistic and scientific value of Ilhéu de Vila Franca is strongly reduced because of tourism. Thus, opening up the Lagoa for tourism could be disastrous for the fauna too. Therefore, in view of the unique origin, geology, fauna, and flora, the place should be declared a "Site of Special Scientific Interest" (Morton and Tristão da Cunha 1993).

ACKNOWLEDGMENTS

We are indebted to B. Morton (University of Hong Kong) and R. Tristão da Cunha (University of the Azores, Portugal) for helping to collect the Azorean *T. decussatus*. J. Troncoso (University of Vigo, Spain) provided us with the Ria population. Financial support was received from the EC program "Biodiversidade no Arquipélago dos Açores" PRAXIS XXI (EUJNICT) 2/2.1/BIA/169/94. S. V. D. and H. D. W. are FWO fellows.

LIFE HISTORY AND HABITAT OBSERVATIONS OF SOFTSHELL CLAMS *MYA ARENARIA* IN NORTHEASTERN NEW JERSEY

CLYDE L. MACKENZIE, JR.,[1] AND SHAWN M. MCLAUGHLIN[2]

[1]*National Marine Fisheries Service, National Oceanic and Atmospheric Administration, James J. Howard Marine Sciences Laboratory, Highlands, NJ 07732*

[2]*National Marine Fisheries Service, National Oceanic and Atmospheric Administration, Cooperative Oxford Laboratory, Oxford, MD 21654*

ABSTRACT Population densities, survival, factors associated with mortalities, and growth of softshell clams, *Mya arenaria*, in two northeastern New Jersey estuaries were studied from 1993 through 1997. The study areas were near shore where low-tide water depths ranged from 15 to 90 cm. Juvenile densities were high only in 1993. Light sets of juveniles from 1994 to 1997 disappeared by the end of their first summer. The longest living softshells were the abundant 1993 year class, which survived for 26 mo in the Shrewsbury River. This contrasts with life spans of 7–12 years for softshells in New England. Mortalities of softshells were correlated with: (1) predation by the striped killifish, *Fundulus majalis*, and mummichog, *F. heteroclitus;* (2) mats of sea lettuce, *Ulva lactusa*; and (3) high temperatures (30–32 °C). Softshell sarcoma was also present and may have contributed to mortalities. The effects of the mortality agents varied among locations and years. The softshells of the Shrewsbury River averaged about 23 mm and 40 mm long at the end of their first and second growing seasons, respectively.

KEY WORDS: *Mya arenaria*, settlement densities, survival, mortality factors, growth

INTRODUCTION

The softshell clam, *Mya arenaria*, ranges along the Atlantic coast of North America from Labrador (Abbott 1974) to Georgia (Rasmussen and Heard 1995), with the highest abundances located from the Bay of Fundy to Chesapeake Bay. The species also occurs in Europe and has been successfully introduced to the coasts of western North America (Abbott 1974). Investigators in New England commented on the wide variations in magnitude of annual sets and on the subsequent survival of softshells (Belding 1930, Turner 1949, Turner 1950, Brousseau 1978b). Softshells can live as long as 7 y (Brousseau 1978b) to 12 y (Belding 1930). Most postsetting mortalities of softshells are caused by predation by shrimp, fish, ducks, brachyuran crabs, xiphosuran crabs, and naticid snails (Belding 1930, Turner 1949, 1950, Foley and Taber 1952, Glude 1955, Smith et al. 1955, Cronin and Hall 1968, Palmer 1976, Edwards and Huebner 1977, Kelso 1979, Holland et al. 1980, Commito 1982, Hines et al. 1990, Eggleston et al. 1992, Rasmussen and Heard 1995), and by breakage and displacement in storm-exposed areas (Kellogg 1910, Belding 1930, Turner 1950, MacKenzie and Stehlik 1988). Investigators in Europe also have reported on the wide annual variability in densities of softshell juveniles and on their subsequent survival and causes of mortality (DeVlas 1979, Beukema 1982, Pihl 1982, Moller and Rosenberg 1983, Kube 1996).

Epizootics of softshells reported from New England to Chesapeake Bay have been associated with disseminated sarcomas (Barry and Yevich 1972, Farley 1976, Yevich and Barszcz 1977, Brown et al. 1977, 1979, Farley et al. 1986, Brousseau 1987, Barber 1990). The proliferative condition is transmissible, progressive, and usually fatal (Brown 1980, Cooper et al. 1982, Farley et al. 1986). The etiology of softshell sarcoma is uncertain; environmental factors (Barry and Yevich 1972, Yevich and Barszcz 1977) and a viral agent (Oprandy and Chang 1981) have been suspected.

The Navesink and Shrewsbury Rivers and nearby Raritan Bay in northeastern New Jersey have produced softshells since prehistoric times (MacKenzie 1990, MacKenzie 1992), but in recent years the stocks have been small, and, consequently, commercial production usually has been small or nonexistent. Previous studies of the softshells in this area have described abundances (Dean 1975), longevity (Appeldoorn 1983, Appeldoorn 1995), abundances and effects of storms (MacKenzie and Stehlik 1988), and the incidence of sarcoma (Barber 1990). Our study was undertaken to characterize annual recruitment, survival, factors that cause mortality, and growth.

Study Areas

The study areas were in the Navesink and Shrewsbury Rivers, in New Jersey (Fig. 1). The primary study site in the Navesink River was off its southeast shore. The site comprised about 3 acres of firm muddy-sand bottom and extended from near the shore edge to about 75 m offshore; water depths were from 15–90 cm at low tide. The mean tidal amplitude is about 1.7 m (Jeffries 1962). Mats of sea lettuce, *Ulva lactuca*, formed in the site, and their aerial distributions varied widely among years. The study site in the Shrewsbury River was off its northeast shore at a similar shore position and water depth, and its bottom sediments were similar. It was about 1 acre in size. Little sea lettuce grows in that section of the river. A reason for selecting the two sites was convenient access to the shore by foot as most all the shoreline areas of the two rivers are private property. The softshells in the two rivers are subtidal.

The identified predators of softshells in the two rivers were: the striped killifish, *Fundulus majalis;* the mummichog, *Fundulus heteroclitus;* and the blue crab, *Callinectes sapidus*. Schools of striped killifish and mummichogs were nearly always present in the study sites, except during the lowest tides, from at least mid-May into October. The blue crabs were scarce in the rivers from 1993 to 1996, but were more abundant in 1997.

During this study, the salinity at the Navesink River site ranged from 15 to 25 0/00, and at the Shrewsbury River site from 20 to 25 0/00. Water temperatures were mostly 11–12 °C during early May, 18–20 °C during June, and peaked at about 25 °C in late July and early August, but in mid-afternoon during late July-early August, 1995, water temperatures ranged from 30.0 °–31.8 °C. Temperatures afterward cooled.

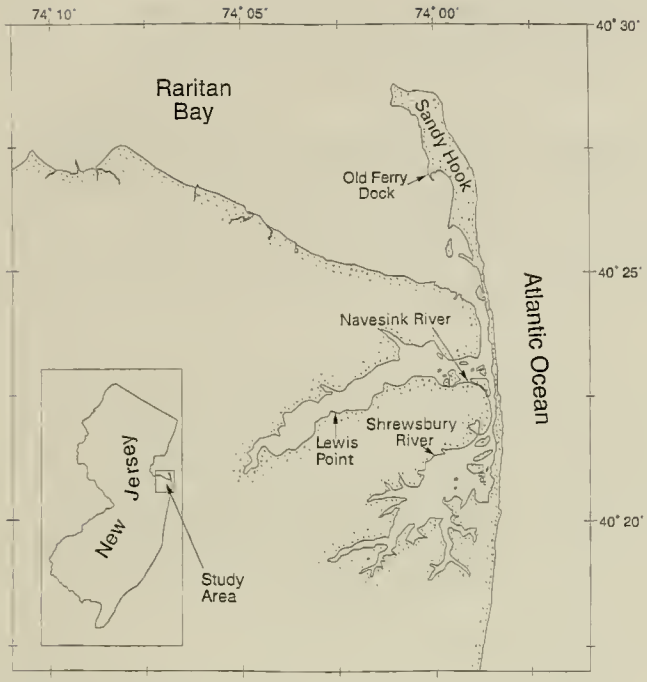

Figure 1. Locations of study and sampling sites in northeastern New Jersey.

The waters of the Navesink and Shrewsbury Rivers interchange with Raritan Bay, which is contaminated with many types of pollutants (Pearce 1983, Breteler 1984). The pollutants consist of suspended particulates, oil and grease, many toxic trace metals, polynuclear aromatic hydrocarbons, polychlorinated biphenyls, DDT, and dioxins (Stanford and Young 1988, Wolfe et al. 1996). In 1974, the copper concentration in western Raritan Bay bottom water was 65 parts per billion (ppb), the highest reported for any estuary; the copper concentration in the surface water there was 36 ppb, and in mid-Raritan Bay it was 7.9 ppb (Waldhauer et al. 1978). In 1992, the copper concentration in the surface water was considerably lower: 4.6 ppb in western Raritan Bay, and 4.3 ppb in mid-Raritan Bay (Anonymous 1992). The bay has extremely high primary productivity with the annual value in the 1970s at 817 g C/m^2, which was considered among the highest of any estuary (O'Reilly et al. 1976). In the 1960s, Raritan Bay was classified as an advanced eutrophic system (Federal Water Pollution Control Administration 1967), but since the 1970s its water quality has improved (Brosnan and O'Shea 1995). Elevated nitrogenous wastes nevertheless continue to stimulate the growth of dense phytoplankton blooms (Draxler et al. 1984, Brosnan and O'Shea 1995); Draxler et al. (1984) had reported Secchi disc readings in the bay of < 1.0–2.0 m during most of the spring and summer. Steimle and Caracciolo-Ward (1989) have shown that the density and diversity of benthic macrofauna in Raritan Bay are relatively low compared with other U.S. east coast estuaries. Similar determinations of pollution, phytoplankton blooms, and macrofauna have not been reported in the Navesink and Shrewsbury Rivers.

The eutrophication of waters probably was responsible for producing some large mats of sea lettuce observed in the two rivers. As Hull (1987) noted, sea lettuce begins as tiny leaves attached to shells and other objects in the spring, grows and persists as thick mats during the summer, and then nearly disappears in the late fall.

METHODS

Sampling Procedures

Field observations lasted 5 y, 1993 to 1997. Water salinity was determined quarterly by titration. Surface water temperatures were measured with a hand-held thermometer daily at 7:30 AM at the Navesink River study site from May into September in 1994, 1995, and 1996. In 1993, following heavy sets of softshells, densities of this year class were estimated once a month, except in the coldest parts of the year, in the Navesink and Shrewsbury River study sites, by placing a ring that encircled a 0.28 m^2 area on the substrate and then removing all softshells for counting and measuring. Three such samples were taken for each determination. From each monthly sample, a subset of 100 softshells, was measured and lengths were plotted to determine growth rates. In 1994, samples to determine the densities of young-of-the-year (juvenile) softshells were taken similarly at each site. In 1995, 1996, and 1997, three 0.28-m^2 areas or six 0.1-m^2 areas were sampled at each site. Only two to three samplings were made in each year from 1994 to 1997, because the low densities of juvenile softshells fell quickly to nearly zero per sample following the initial samplings in June or July.

Potential predators of softshells were collected by pulling a fine-mesh, 15-m seine for about 60 m over an inshore section of bottom in the study sites in the Navesink and Shrewsbury Rivers. A single seining was made at each site at half tide during the outgoing tide in July 1994. Fish and shrimp were collected, but only the fish were examined. They were placed in a plastic bag, held on ice in a cooler, and frozen the same day. Later, they were thawed, and the invertebrates, plants, and other contents in their stomachs and guts were identified and counted using a dissecting microscope.

Field Experiment on Fish Gut Evacuation

During August 1996, an experiment was conducted to determine the evacuation rate of food from the stomachs and guts of the mummichog, *F. heteroclitus*. One hundred mummichogs (mean length 79.1 mm; range 63–110 mm) were seined and divided into five groups of 20 each. The first group of fish was immediately iced, then frozen, and later thawed and examined for the quantity of food in their guts. The other four groups were held in separate field cages suspended above the bottom for 3, 6, 9, and 24 h at temperatures of 23.5 °–25.0 °C and then processed similarly to the first group. A visual estimate was made of gut fullness.

Diagnosis of Sarcomas

The prevalences of softshell sarcomas were determined using histological methods (Farley et al. 1986). Samples of 50 softshells, 40–55 mm long, were collected quarterly at four sites, namely, our two primary study sites in the Navesink and Shrewsbury Rivers, at Lewis Point (5 km west of our primary study site in the Navesink River), and in Raritan Bay at the Old Ferry Dock on the west side of Sandy Hook (Fig. 1). The collections eventually ended in the Navesink and Shrewsbury Rivers because the softshells had died or had became too scarce. Following collections, the softshells were transported to the Cooperative Oxford Laboratory, Oxford, MD. Hemolymph was drawn from the adductor muscles into sterile syringes containing ambient sterile seawater, expelled into slide chambers, and fixed after 30 min in 1 glutaraldehyde-4 formalde-

hyde. The hemolymph preparations were stained with fuelgen picromethyl and were examined for sarcomas by light microscopy.

RESULTS

Navesink River

The setting densities of juvenile softshells in our Navesink and Shrewsbury River study sites were similar to one another each year. The juveniles were relatively abundant in the two rivers only in 1993. In the Navesink River, they had set throughout the shallows over a distance of 10.5 km off its south and northwest shores. At the study site, their density at the initial sampling in August 1993 was 1,110/0.28 m^2. Their survival after that was fairly high: 60–69% were alive in late April to late May 1994 (Table 1).

In 1993, sea lettuce was relatively sparse in the study site, but by mid-June to early July 1994, a solid mat of sea lettuce had formed. The mat was about 25 cm thick and extended from the shore outward to cover about half of the 3-acre bed. In addition, some isolated stationary sea lettuce mats, as small as 2 m across, formed in areas beyond the main mat. All the observed 1993 year class of softshells covered by the mats initially extended their siphons several centimeters out of the sediment, then emerged from it, laid on its surface beneath the mat, and died. In contrast, the softshells in unvegetated areas did not extend their siphons, emerge, and die.

From 1994 through 1997, the sets of juvenile softshells were light in the river. In 1994, the unvegetated sediments outside any sea lettuce mats received a set of juveniles; on June 30 of that year, they had a mean density of 54.7/0.28 m^2 (three replicates, SE 9), but by July 8, 1994, their density had fallen to 2.3/0.28 m^2 (three replicates, SE 0.7). The 1995 and 1996 sets were much more sparse than those in 1994 and 1997. On July 28, 1997, the 1997 juveniles had a mean density of 28.8/0.10 m^2 (six replicates, SE 4.7), but by August 9, 1997, their density had fallen to 3.7/0.10 m^2 (six replicates, SE 0.6). Subsequent samplings in August and September each year from 1994 to 1997 found few juveniles in the site.

On July 7, 1994, when the density of the 1994 year class of softshells was declining rapidly, a seining was made over the bed to examine the stomachs and guts of fish. Forty-one of 60 striped killifish (average length 64 mm, range 46–78 mm) contained an average of 46 juvenile softshells/fish (range 1–169 softshells), and one of three mummichogs (average length 97.3 mm, range 84–115 mm) contained two juvenile softshells. The softshells ranged from 2–11 mm long. The remaining striped killifish and mummichogs had food in their stomachs but no softshells.

Shrewsbury River

In 1993, softshells set densely in the shallows along most of the north shore of the Shrewsbury River in a band about 7 m wide, over a distance of about 4.2 km. The density of the 1993 year class of softshells at the study site at the initial sampling in October 1993 was 849/0.28 m^2. After that, their survival was fairly high, as 54–67% were alive in late April-early June 1995 (Table 1). By August 7, 1995, about 26 months after setting, this entire year class of softshells was dead at the site. They died during a period of unusually high air and water temperatures in late July-early August. At 3:00 PM on July 31, the water temperature was 31.8 °C, the softshells were dying and rotting, and the water over the bed was a yellow-brown mixture of rotting softshell meats and brown phytoplankton. Their mortality apparently was caused by the high temperatures, because the lethal temperature of adult softshells is in the temperature range of 30.5 °–32.5 °C (Kennedy and Mihursky 1971).

From 1994 through 1997, juvenile softshells were relatively scarce throughout the river. At the study site, the small numbers observed by scraping with a sieve through the surface of sediments in 10 places in June and July disappeared by August or September in the years in which they set, similarly as the light sets had disappeared in the Navesink River.

On July 8, 1994, fish were seined at the study site and their guts were examined for softshells and other foods. Four striped killifish (average length 107 mm, range 92–113 mm) contained an average of 26 juvenile softshells/fish (range 21–32 softshells per fish); 123 of 150 mummichogs (average length 69 mm, range 40–93 mm) had an average of 15.5 juvenile softshells per fish (range 1–53 softshells per fish); and one spot, *Leiostomus xanthurus*, had 115 juvenile softshells. The softshells ranged from 4 to 11 mm in length for all fish. Other items in the guts of striped killifish and mummichogs in the Navesink and Shrewsbury Rivers were: juvenile common Atlantic slippersnails, *Crepidula fornicata;* amphipods; isopods; juvenile horseshoe crabs, *Limulus polyphemus* (about 3 mm carapace width); polychaetes; sea lettuce; and detritus.

Food Passage Through Mummichogs

Mummichogs passed food through their stomachs and guts rapidly (Fig. 2). In the experiment to estimate the rate, a large decline (80%) in fullness of their guts was evident after 3 h, and little food remained after 24 h. The results suggest that the softshells found in mummichogs that were seined at the sites were eaten within 24 h, and they imply a high consumption rate.

Histology

In the Navesink River, quarterly samples showed a low sarcoma prevalence in 1994, but prevalence reached 18% in December 1995 and decreased slightly to 13% and 14% for the first two quarters in 1996, while samples from Lewis Point were negative for sarcomas in 1991 to 1993 (Table 2). In the Shrewsbury River, quarterly samples of softshells examined for sarcomas were negative in 1994 and 1995. At the Old Ferry Dock, in collections in

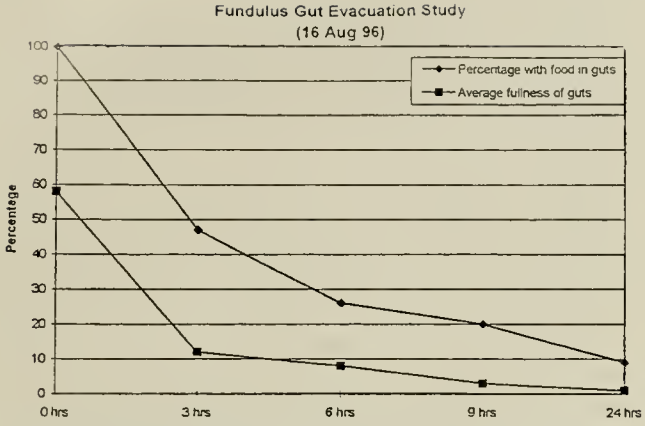

Figure 2. Percentage with food in guts and average fullness of guts of *F. heteroelitus* held in field cages at spaced intervals, 0–24 h.

1995, 1996, and 1997, from 10–20% of softshells were infected with sarcoma on four of seven dates, and from 0–4% were infected in the remaining three dates.

Growth

The length-frequency curves for the 1993 year class of softshells in the Navesink and Shrewsbury Rivers are presented in Figure 3. The curves for each time period show a single mode that broadens somewhat as time passes. In the Navesink River, the softshells had a mean length of 15.4 mm in September 1993, 22.1 mm in November 1993, and 31.6 mm in May 1994. In the Shrewsbury River, their mean lengths were 19.3 mm in October 1993, 22.9 mm in November 1993, 26.6 mm in April 1994, 38.9 mm in November 1994, 47.6 mm in April 1995, and 48.9 mm in June 1995.

DISCUSSION

In attempting to find reasons for the large annual variability in setting densities of softshells in Europe, Beukema (1982, 1992), Jensen and Jensen (1985), and Moller (1986) observed that heavy sets of softshells and some other bivalves occurred during summers following cold winters and that light sets followed mild winters. The bivalves were active during the mild winters when little food was available in the water, and they consequently had absorbed most of their gonads by the time spawning began in the spring. Our study was not continued sufficiently long enough to document such a correlation, but it is likely that dense sets of softshell juveniles result from certain weather conditions. The spring and early summer of 1993 when the heavy sets occurred in the Navesink and Shrewsbury Rivers did feature weather with no cold easterly winds with rain. During the springs and summers of 1994 to 1997, however, when light sets occurred, several periods of cold easterly winds and rain, each of 3–4 days duration, were interspersed with periods of warmer westerly and southerly winds. Belding (1930) had noted that the numbers of larvae in the water declined during periods of cold rains.

Earlier investigators have noted the disappearances of softshell

juveniles by the end of their first summer in some years (Brousseau 1978a, Moller and Rosenberg 1983, Beukema 1979, Pihl 1982). We believe that predation by striped killifish and mummichogs was the principal reason for the sharp declines and disappearances of juveniles in our study sites during 1994 to 1997. The observations suggest that any relatively light sets of softshells, as dense as 500/m^2 or even higher, could be lost to such predation every year whenever the fish are abundant in the two rivers. The fish likely were present and preyed on juvenile softshells in 1993, but perhaps the juveniles were so abundant that a great many remained alive by the time they had grown too large for the fish to prey on them.

Fish also prey on softshells in other regions. Kelso (1979) described heavy predation of juvenile softshells by mummichogs in Massachusetts. In our study, the sizes of softshells (2–11 mm long) taken by the striped killifish and mummichogs were similar to those that Kelso (1979) reported; probably 11 mm is near the maximum size of a softshell that the fish can devour. More softshells were present in the guts of mummichogs in the Navesink River (about 46 softshells per fish) than he found in Massachusetts (6–9 softshells per fish). Perhaps the softshells were more abundant in the Navesink River. Medcof and McPhail (1952) stated that adult winter flounders, *Pleuronectes americanus*, about 28 cm long, consumed whole juvenile softshells and nipped off the siphon tips of adult softshells in eastern Canada. In their study, the softshells with nipped siphons recovered without unusual mortality. Rasmussen and Heard (1995) stated that Atlantic stingrays, *Dasyatis sabina*, feed on softshells in Georgia. Pihl (1982) and Moller and Rosenberg (1983) observed that flounders *Platichthys flesus* consume large numbers of juvenile softshells, 2–12 mm long, in Sweden, and DeVlas (1979) observed that flounders *P. flesus* and plaice, *Pleuronectes platessa*, consume juvenile softshells and the siphon tips of older softshells in the Netherlands. Summer flounders, *Paralichthys dentatus*, and other fish were present in the Navesink and Shrewsbury Rivers and might have preyed on softshells, but they were not observed or collected during our visits to the study areas.

Relatively scarce in our study sites from 1993 to 1996, blue crabs appeared to be a minor predator then, but they were abundant and may have killed many juvenile softshells in 1997. Since our observations were limited to periods of low and mid tides and during daylight, blue crabs and other predators may have entered the study sites and eaten some juveniles during high tides and at night during all years. Green crabs, *Carcinus maenas*, and naticid snails, both predators of softshells in New England (Belding 1930, Glude 1955, Smith et al. 1955, Edwards and Huebner 1977, Commito 1982), were not observed in the two rivers during 1993 to 1997 and could not have caused much mortality of the softshells. Horseshoe crabs, also a softshell predator in New England (Turner 1949, 1950), were scarce and apparently killed few softshells in the two rivers. The shrimp, *Crangon crangon*, preys on softshells as large as 3 mm long in Europe (Moller and Rosenberg 1983). The seven-spine bay shrimp, *Crangon septemspinosus*, and the marsh grass shrimp, *Palaemonetes vulgaris*, were abundant in our two study areas but were not examined as predators of small postset softshells, and neither were amphipods and isopods.

In eastern North America, greater scaup, *Aythya marila*, prey on a variety of small clams, including softshells, blue mussels, *Mytilus edulis*, and snails (Foley and Taber 1952, Cronin and Hall 1968, Barclay pers. commun., 1998). Black ducks, *Anas rubripes*, prey on bivalves, including *Macoma balthica*, blue mussels, and marine snails, such as eastern mud snails, *Ilyanassa obsoleta* (Palmer 1976). Greater scaup and black ducks were present in the Navesink and Shrewsbury Rivers, but there were no signs that they ate softshells in our study areas.

Juvenile softshells also can be killed on exposed shallow habitats during wind storms by having their thin shells ground into fragments or being washed onto nearby beaches (Kellogg 1910, Belding 1930, Turner 1950, MacKenzie and Stehlik 1988). This type of mortality was not observed in our Navesink and Shrewsbury River study sites, but it was observed in the softshells that had set along the south shore of Raritan Bay.

Once past their first summer, softshells can survive fairly well as long as exogenous mortality factors are absent, as shown by Belding (1930) and Brousseau (1978b) in New England, Kube (1996) in Europe, and others. In the Navesink River, the 1993 year class of softshells survived well from September 1993 through May 1994 until mats of sea lettuce killed them, and in the Shrewsbury River it survived well from October 1993 through June 1995 when shortly afterward high temperatures apparently killed them. The age of the Shrewsbury River softshells when they died, 26 mo, was the maximum that any lived in the two study sites and is far shorter than softshells lived in New England where their habitat was undoubtedly much better (Belding 1930, Hanks 1963, Brousseau 1978b). Appeldoorn (1995) stated that softshells in the Navesink River could live at least 15 years around the time of his sampling (1977), but his finding was based on shell markings and sizes of softshells found during a single collection and might be in error. Nevertheless, in an earlier paper, Appeldoorn (1983), reporting on the same 1977 samples, stated that softshells were present as large as 78 mm long or even larger and were obviously older than the largest softshells (62 mm) that we found in the Navesink and Shrewsbury Rivers. The environmental conditions in the two rivers during 1993-1997, such as extremely high temperatures in 1995, apparently did not allow the softshells to live as long as they did during the 1970s.

Some earlier workers had shown that algal mats grow over and kill bivalves, but our study may be the first to document that mats of *U. lactuca* kill softshells. Thiel et al. (1998) had similarly found that overgrowths of the filamentous alga *Enteromorpha prolifera* kill softshells in Maine; Breber (1985) found that mats of *Ulva rigida* and *Gracilaria* sp. kill carpet-shell clams, *Tapes decussatus*, in Italy; and Everett (1994) showed that the bent-nose macoma, *Macoma nasuta*, was more abundant in areas devoid of *Ulva expansa* than in areas where it formed mats in California. The same condition probably develops under *U. lactuca* mats that Gray (1992) described under *U. rigida* mats in Europe: Anaerobic conditions are reached and sulfide and other toxic compounds are produced leading to a massive mortality of benthic organisms.

Sarcoma infections occur seasonally (Farley 1976, Farley 1989, Cooper et al. 1982, Brousseau 1987, Barber 1990). Perhaps in collecting the softshells quarterly, we missed detecting some sarcoma in them. During most collections of adult softshells, a few recently dead specimens with whole shells were noticed among the 100–200 that were taken. Sarcoma might have been responsible for some mortality that was not identified to cause, or perhaps the softshells died from some other cause. We were unable to determine whether contaminants in the waters and sediments and dense phytoplankton blooms affected the longevity of the softshells. Barber (1990) found sarcomas in softshells in the Shrewsbury River in 1986 and 1987 and concluded that annual mortality due to the

disease was about 3.5% at that time. Our study cannot add much to his estimate.

The sizes of softshells at certain ages that Appeldoorn (1983) suggested for the Navesink River correspond with our findings in the Shrewsbury River. For example, at 20 months of age the softshells that Appeldoorn measured were 42.5 mm long and at 28 months they were 47.3 mm long, or similar to the mean lengths of softshells in the Shrewsbury River at about the same ages in November 1994 and June 1995. However, the comparisons are too crude to compare actual growth rates in the 1970s and the 1990s.

The small and sporadic commercial harvests of softshells in this area likely are due to their low setting densities and poor survival rates in recent years. The softshells probably would survive longer if a period of cooler summers and reduced eutrophication of waters were to follow.

QUAHOG PARASITE UNKNOWN (QPX) IN THE NORTHERN QUAHOG *MERCENARIA MERCENARIA* (LINNAEUS, 1758) AND *M. MERCENARIA* VAR. *NOTATA* FROM ATLANTIC CANADA, SURVEY RESULTS FROM THREE MARITIME PROVINCES.

Fisheries and Oceans Canada
Gulf Fisheries Centre
PO Box 5030
Moncton, NB E1C 9B6

ABSTRACT A histology based survey of 3047 quahogs from various sites in three Atlantic Canadian provinces between 1990–98 revealed Quahog Parasite Unknown (QPX) in clams ranging from 18–92 mm in length (> 1.5 years old). Prevalences ranged from 1.7% in wild quahogs to 80% in hatchery broodstock. An additional two year (1996–97) seasonal survey of four sites (St. Andrews and Shediac Bridge, New Brunswick; Wallace, Nova Scotia; and West River, Prince Edward Island) found QPX in quahogs 43–102 mm in length (n = 715) at Wallace (% P = 6.7%) and St. Andrews (% P = 20%). Infections were found in spring, summer and fall samples and no significant difference was found between male and female infected quahogs at either site (1996–97; χ^2, $P > 0.10$). The most commonly infected tissues were the gills, mantle and gonads.

KEY WORDS: Quahog Parasite Unknown (QPX), *M. mercenaria*, *M. mercenaria* var. *notata*, pathology

INTRODUCTION

Quahog Parasite Unknown (QPX) infects the hard-shell clam (northern quahog) *Mercenaria mercenaria* and the selected variety, *M. mercenaria* var. *notata* (Chanley 1961). It has caused cumulative mortalities ranging from 80% in quahogs from New Brunswick (Drinnan and Henderson 1963), and Cape Cod, Massachusetts (Smolowitz et al. 1998) to 100% in hatchery broodstock in Prince Edward Island (Whyte et al. 1994; Bacon et al. 1999). It also occurs in apparently healthy quahogs from Atlantic Canada and Virginia (McGladdery et al. 1993; Ragone Calvo et al. 1998). QPX has also been associated with quahog mortalities from Burton Bay, Virginia (Ragone Calvo et al. 1997). The Gulf of St. Lawrence is the northern-most limit of *M. mercenaria*, thus the clams may respond differently, both in terms of growth and disease resistance, from clams in the middle of their geographic distribution in the U.S. The conditions which trigger pathogenic infections levels, however, have yet to be determined.

Recent interest in developing the northern quahog for aquaculture in Atlantic Canada revealed a lack of base-line information on normal parasite and disease profiles for this species. Because culture involves handling and holding the clams in unnatural conditions, QPX has the potential to become a significant health problem, especially as hatchery broodstock are developed (Whyte et al. 1994). An accurate understanding of the seasonal and geographic distribution of QPX in wild and cultured populations throughout Atlantic Canada was, therefore, required. Throughout the past 10 years, samples of wild and cultured quahogs have been examined histologically for parasites and pathology, including QPX, as part of diagnostic services provided by Fisheries and Oceans Canada, Gulf Fisheries Centre, Moncton, New Brunswick. These data, in addition to a seasonal histological survey of wild quahogs from four sites in New Brunswick (NB), Nova Scotia (NS), and Prince Edward Island (PEI), conducted between 1996 and 1997, were examined to determine if there were significant population differences in quahog health profiles. Unlike other bivalve species cultured to date, quahogs in Atlantic Canada have undergone relatively little transfer and population mixing. This was, therefore, seen as an opportune time to collect base-line health information for subsequent development of the quahog aquaculture industry.

MATERIALS AND METHODS

Diagnostic Survey 1990–98

A total of 3047 quahogs was examined (Table 1). Quahogs (wild and *notata* variety) were collected or shipped live from aquaculture sites and hatcheries in NB, NS and PEI (Table 1) to the Gulf Fisheries Centre, Moncton, within 12–24 h of collection. Anterior-posterior length (mm) and weight (in shell) were measured before shucking. A 2–3 mm dorso-ventral cross-section was removed and fixed in 1% gluteraldehyde/ 4% formaldehyde (Howard and Smith 1983) for light microscopy. The tissues for light microscopy were paraffin embedded, sectioned (6 μm) and stained using Harris' hematoxylin and eosin.

Tissue sections were examined at 25 and 250 magnification using a Leitz Dialux 20 compound microscope. Prevalence of QPX was recorded, along with a qualitative scale for intensity of infection (light = < 25; organisms, moderate = 25–50 organisms; and heavy = > 50 organisms) per tissue section. The sex ratio of mature quahogs, infected with and without QPX, was compared to a 1:1 ratio using a standard Chi Square test (Zar 1984) to determine if there was any relationship between quahog sex and presence of QPX.

Seasonal Survey 1996–97

Wild quahogs were collected during the spring (May/June), summer (August) and fall (October/November) of 1996 and 1997 from: (1) St. Andrews, NB; (2) Wallace, NS; (3) West River, PEI; and (4) Shediac Bridge, NB (Figure 1). Samples of 28–30, total = 715, quahogs were collected and processed as described above, between May, 1996 and October, 1997 (Table 2). Water temperature and salinity were taken at the time of collection from all four sites during both years. In addition, a continuous temperature recorder was placed at the Wallace location from May to October 1996 and 1997. The sex ratio of infected quahogs was compared to a 1:1 ratio using a standard Chi-Square test (Zar 1984).

RESULTS

Diagnostic Survey 1990–98

No gross clinical signs were observed in any of the quahogs examined for the diagnostic survey, including clams with high intensities of infection detected using histological examination. QPX was found in *M. mercenaria* and *M. m.* var. *notata* from all three provinces. Prevalences ranged from 1.7% in wild quahogs from Pugwash, NS, in 1997, to 80% in moribund broodstock from the Ellerslie hatchery, PEI, in 1990 (Table 1). Of 3047 quahogs examined, 64 showed evidence of QPX infection (% P = 2.2) (Figure 2). Intensity of infection ranged from light to heavy. The size range of quahogs infected by QPX ranged from 18.3–92.5 mm (Table 1). The sex ratio of infected quahogs was 30 male:18 female:16 undetermined (resting stage or immature), which was not significantly different from 1:1 (χ^2, $P > 0.10$). The sex ratio of uninfected clams, however, was significantly different from 1:1 (996 male: 862 female: 1125 unidentified (resting stage or immature); χ^2, $P < 0.005$).

Of all the infected clams, the most commonly infected tissues were the gills (34%), mantle (31%) and gonads (31%) (Table 3). The digestive gland and foot were less commonly infected (12 and 5%, respectively).

Seasonal Survey 1996–97

No gross clinical signs were observed during necropsy of the quahogs collected for the seasonal survey. Clams from two of the four sites showed evidence of QPX infections: Wallace (1996 only) and St. Andrews (1996 and 1997) (Table 2). The summer sample of quahogs from Wallace had a prevalence of 6.7% QPX (light intensity). Quahogs from St. Andrews showed prevalences of QPX ranging from 3.3% (spring and fall, 1996), at light intensities, to 20% (summer 1997) at heavy intensities (Figure 3).

Figure 1. Map of Atlantic Canada showing sampling sites positive for QPX from all surveys and diagnostic material examined. The circle denotes the 1959–63 QPX study of Drinnan and Henderson (1963), diamonds denote the 1990–98 diagnostic survey, stars denote the 1996–97 survey and triangles show sites with QPX in hatchery broodstock. The dashed lines represents the northern-most limit of *M. mercenaria*.

The mean sample lengths of the quahogs examined (n = 715) ranged from 60.0 (± 10.7) to 83.5 (± 6.3) mm in 1996 and 61.9 (± 9.9) to 83.2 (± 4.9) mm in 1997. It was difficult to tell whether the same cohorts were sampled over the two year seasonal survey, because quahogs grow slower, once mature, in cooler northern waters than in warmer waters to the south. The highest water temperatures occurred in August at all sites and temperature ranges (8–24°C) were relatively consistent between sites for both years (Table 2). All four sites had moderate to high salinities (20–32‰) which were consistent over the survey period (Table 2). The highest prevalence (20%) was found in clams from St. Andrews in the summer of 1997 (Table 2). The second highest prevalence (13.3%) was found in the spring, 1997, sample. QPX was detected in one sample of clams from Wallace, in the summer of 1996 (6.7%). The temperature recorder on the Wallace bed recorded air temperatures, at low tide, as low as 0 °C in May, 1996 and as high as 34 °C in August, 1996 and 1997. The sex ratio of QPX-positive quahogs was 5 male:1 female in 1996 and 8 males:4 females in 1997, which was not significantly different from 1:1 (χ^2, $P > 0.10$, 1996 and $P > 0.25$, 1997). The sex ratio of uninfected clams was 173 male: 178 female: 1 unidentified (resting stage or immature) in 1996, and 187 male: 159 female: 1 unidentified (resting stage or immature) in 1997, which was not significantly different from 1:1 (χ^2, $P > 0.90$, 1996 and χ^2, $P > 0.10$, 1997). Of the infected clams, the most commonly infected tissues were the gonads (28%) and mantle (22%), although the digestive gland and foot (17%) and gills (11%) also showed high levels of infection (Table 3).

DISCUSSION

QPX or QPX-like organisms were first found in Atlantic Canada in the late 1950's/ early 1960's in wild *M. mercenaria* from Neguac, NB (Miramichi River estuary) in the Gulf of St Lawrence (Drinnan and Henderson 1963). Prevalences ranged from 50% in weak and dead quahogs to 5% in apparently healthy quahogs (Drinnan and Henderson 1963). Accumulated mortalities in grow-out tests conducted between 1959 and 1960 ranged from 60–90% in native quahogs to 20–25% in apparently healthy quahogs transplanted from nearby Miramichi beds (Drinnan and Henderson 1963). QPX was not investigated further until the early 1990's when it was found in moribund quahogs (15–30 mm in length) being conditioned for spawning at a hatchery in PEI (Whyte et al. 1994). The connective tissue and muscle were found to be infected with "an invasive eukaryote organism" identical to that described by Drinnan and Henderson (1963) and was given the non-taxonomic acronym "QPX" for "Quahog Pararsite Unknown" (McGladdery *et al.* 1993; Whyte et al. 1994).

QPX or QPX-like organisms have been found in quahogs from New Jersey in 1976 (Smolowitz et al. 1998) and more recently in quahogs from Virginia (Ragone Calvo *et al.* 1997, Ragone Calvo *et al.* 1998) and Massachusetts (Smolowitz *et al.* 1998). During the summer of 1995, 1.5–2 year old quahogs planted on aquaculture leases in Cape Cod, experienced mortalities with prevalences ranging from 10% in "non diseased" clams to 90% in diseased clams (Smolowitz et al. 1998). Cultured 1–2 year old clams (19–89 mm) from the eastern shore of Virginia ranged from 8–20% in 1996, to 4–48% in 1997, with associated mortalities estimated at 10–20% in the latter (Ragone Calvo et al. 1998).

The Miramichi Estuary of the Gulf of St. Lawrence is the northern-most geographic limit of *M. mercenaria*, thus QPX does not occur in the St. Lawrence River as mentioned in Ford et al. (1997) and Smolowitz et al. (1998). Prevalences of QPX in *M. mercenaria* and *M. m.* var. *notata* in the 1990–98 diagnostic survey ranged from 1.7% in *M. mercenaria* in Nova Scotia, to 80% in broodstock being conditioned for spawning at the Ellerslie Shellfish Hatchery, PEI (Table 1). No mortalities attributed to QPX have been found in wild quahogs in Atlantic Canada since the original cases reported by Drinnan and Henderson (1963), however, open-water mortalities are known to have occurred without being investigated (Drinnan, pers comm.). The highest prevalences of QPX recorded in the 1990–98 diagnostic survey were in both cultured native and *notata* variety broodstock from all three Maritime provinces (Table 1). The 1996–97 survey found 6.7% prevalence of QPX in clams from Wallace, N.S. and 3.3–20% QPX in an isolated native population at St. Andrews. Prevalences in quahogs at both sites were comparable to those found in US wild clams (8–90%, Smolowitz et al. 1998, Ragone Calvo et al. 1997 and 1998).

The size range of infected quahogs in this study ranged from 18 to 110 mm (Tables 1 and 2). Before 1998, the reported size range of QPX infected quahogs was > 35mm shell length. Despite their small size, the 18–25 mm cultured *M. mercenaria* from Vernon River, PEI, had been in the field for one year and were approximately 1.5 years old (Burleigh pers comm.). Ford et al. (1997) examined tissue sections of 2203 seed quahogs (< 1–20 mm and no more than a few months old) from 13 different hatcheries in six States. No evidence of QPX or QPX-like organisms was detected. QPX was also not detected in 756 hatchery-produced quahogs after a year of field grow-out (Ford et al. 1997), thus, it was

concluded that hatchery-produced seed are unlikely to be infected by QPX. Conversely, Whyte et al. (1994) found QPX in infected hatchery-reared quahogs ranging from 15–30 mm in shell length. The report did not distinguish the exact size or age of infected quahogs, and no attempt was made to characterize the relationship between individual quahog size and presence of QPX (Whyte, pers. comm.). Due to colder growing conditions in the Gulf of St. Lawrence, compared with Massachusetts and Virginia, it is possible that the < 20mm quahogs examined by Whyte et al. (1994) could have been the same age as larger quahogs from further south. All QPX findings to date in the US have been from quahogs typically 1 to 2 years-old (Ragone Calvo et al. (1997 and 1998) and Smolowitz et al. (1998)).

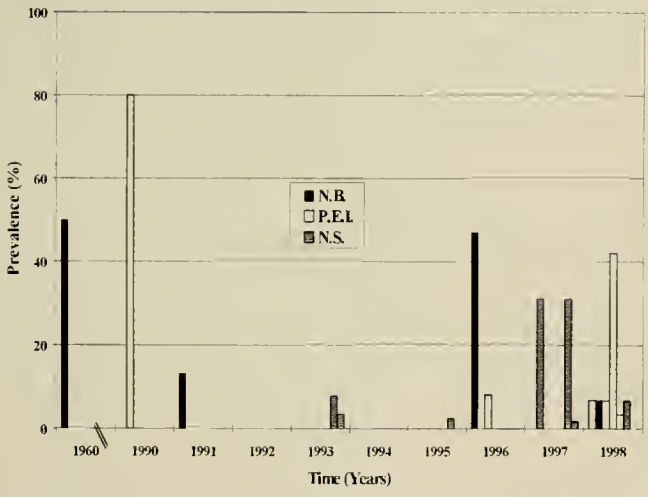

Figure 2. Historical and geographic summary of QPX in *M. mercenaria* and *M. mercenaria* variety *notata* from Atlantic Canada.

The taxonomic affinity of QPX is currently under investigation in both Canada and the U.S. (Smolowitz et al. 1998; Maas et al. 1999). Whyte et al. (1994) suggested that the QPX was similar to the labyrinthulids and thraustochytrids, belonging to the Phylum Labyrinthomorpha (Pokorny 1985). Members of these groups are common saprophytes in marine environments (Porter 1990), and have also been reported to cause disease in a number of molluscs

TABLE 3.

Prevalence of QPX in different tissues of infected quahogs.

Tissues	1990–98 percent of infected clams (n = 64)	1996–97 percent of infected clams (n = 18)
Gill	34	11
Mantle	31	22
Gonad	31	28
Digestive gland	12	17
Foot	5	17

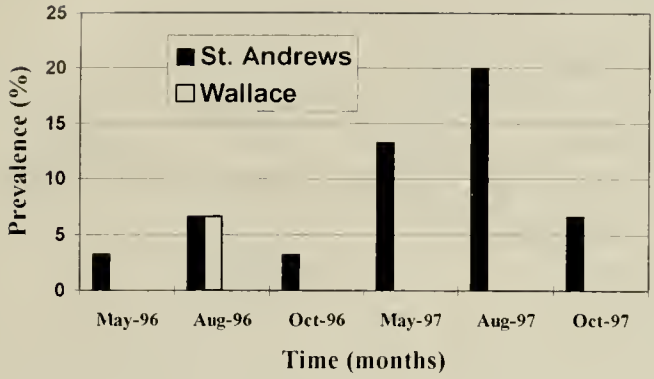

Figure 3. Prevalence of QPX from the two year repeated survey 1996–97. Solid black represents St. Andrews (Sam Orr Pond), N.B.) clams; unfilled box represent Wallace, N.S. clams. Clams from Shediac Bridge, N.B. and West River, P.E.I. were negative for QPX.

(Polglase 1980; McLean and Porter 1982; Jones and O'Dor 1983; Bower 1987a). One Labyrinthulid, *Labyrinthuloides haliotidis*, has been linked to mortalities of up to 100% of nursery-held juvenile abalone, *Haliotis kamtschatkana*, in British Columbia (Bower 1987a). Further investigation found that *L. haliotidis* is transmitted directly from abalone to abalone by a flagellated zoospore stage (Bower 1987b). Motile zoospores have been identified in both Canadian (Whyte et al. 1994) and U.S. (Kleinschuster et al. 1998) QPX cultures, therefore, it is likely that QPX is also transmitted directly. The likelihood of direct transmission would also be expected to be heightened in holding facilities or nurseries where clams are held in close proximity to each other in raceways, downwellers or upwellers. Further research on QPX transmission to both *M. mercenaria* and *M. m* var. *notata* is needed to fully understand the epizootiological potential of this parasite.

Smolowitz et al. (1998) noted thickened, retracted, light tan, swollen mantle edges in diseased clams from Cape Cod. Occasionally, yellow/tan nodules, 1–4 mm in diameter, were also observed along the mantle edges or in the mantle areas adjacent to the anterior adductor muscle. Shell margins were chipped and diseased quahogs showed variable amounts of sand embedded between the mantle edge and shell (Smolowitz et al. 1998). Smolowitz et al. (1998) postulated that shell chipping was a result of quahogs attempting to close their shells on the sand and sediment caught in the quahog's mucus. Soft tissues and shells were examined for all clams used in this study, however, no gross pathological changes have been seen, to date, in infected quahogs from Atlantic Canada, including heavily infected individuals.

Both sexes of quahog were infected with QPX . Prevalences in males were significantly higher than in females in the 1990–98 survey, but no significant differences were found between males and females in the 1996–97 seasonal survey. Uninfected quahogs examined in both surveys had a sex ratio of 1:1. No differences between the sex of infected clams have been reported elsewhere, to date.

The most commonly infected tissues in infected clams from the 1990–98 diagnostic survey were the gills (34%), mantle (31%) and gonad (31%). Similar results were found in the 1996–97 seasonal survey (gonad-28% and mantle-22%). Smolowitz et al. (1998) found that the most commonly infected tissues of infected quahogs from Cape Cod were the mantle (91%) and gill (63%). Ragone Calvo *et al.* (1998) also found the mantle (63%) and gills (35%) to be the most frequently infected tissues in infected quahogs from Virginia. The digestive gland (12–17%) and foot (5–17%) were less commonly infected in both 1990–98 and 1996–97 surveys. Smolowitz et al. (1998) also found the kidney (20–25%), adductor muscle (0–6%), foot (3–13%), digestive gland (0%), ganglia/mantle nerves (0%) and palps (0%) to be less heavily infected. Ragone Calvo *et al.* (1998) also observed infections in the musculature of the foot, sinuses and connective tissue of the kidney and connective tissue of the digestive glands (4, 11, and 15%, respectively). Drinnan and Henderson (1963) found QPX in the gill, kidney, connective tissue, foot, and heart of infected quahogs from New Brunswick but did not differentiate between levels of infection and tissue site. Although not quantified for this study, we found no evidence of palp, nerve or adductor muscle infections.

There are at least three environmental factors which may favour the proliferation of QPX in both hatchery and wild clams: i) stocking density; ii) water temperature; and iii) genetic susceptibility. Stocking density may have played an important part in the epizootic incident of QPX in wild quahogs from Neguac, N.B. (Drinnan 1961). The typical or natural stocking density of wild adult (> 20 mm) quahog populations in Atlantic Canada is approximately 4–5 clams m^{-2} (T. Landry, Fisheries and Oceans Canada, pers. comm.). Historically some quahog farming operations have planted seed (< 3 mm) at densities ranging from 357–43,011 m^{-2} (Judson et al. 1977; MacPherson et al. 1978; Witherspoon 1984) with no outbreaks of QPX reported. To date, only one report by Kraeuter et al. (1998) has examined the effects of planting density on proliferation of QPX. Juvenile quahogs (< 10 mm) from New Jersey were planted on intertidal and subtidal sites at three densities: 215, 430, and 860 clams m^{-2} per plot. The prevalence of QPX increased during the four-month experiment, but no significant effect, due to density or location, was detected (Kraeuter et al. 1998).

Water temperature and/or salinity may also be significant factors influencing the prevalence of QPX. All four sites in the seasonal survey experienced relatively similar temperature regimes, at the time of collection, ranging from 8 °C (May, 1996, and October, 1997) to 24 °C (August, 1996–97). Salinities ranged from 25–32‰ between 1996 and 1997. The clam beds at St. Andrews, Shediac Bridge and West River are all sub-tidal (1–3 m depth depending on tide level), whereas the Wallace site is completely exposed during each low tide. As a result, seasonal temperatures at the Wallace site, ranged from 8–28 °C (from May to October, 1996 and 1997), with air temperatures reaching as high as 34 °C at low tide. QPX was detected at the St. Andrews location in temperatures ranging from 10–22 °C and salinities ranging between 25–32‰. Historically, water temperatures at the St. Andrews site (Sam Orr Pond) range from –0.1–25 °C (Medcof 1961, S.M.C. Robinson, Fisheries and Oceans Canada, pers. comm.). The single QPX infection detected at Wallace occurred in August, 1996, when the water temperature was 24 °C and salinity was 30‰.

Ragone Calvo et al. (1998) collected quahogs from 18 different sites in Chesapeake Bay and coastal Virginia, where salinities ranged from 15 to 34‰. QPX was only detected in clams from three coastal lagoons, where salinities ranged from 30 to 34‰ (Ragone Calvo et al. 1998). Theses authors point out that the absence of QPX from more moderate salinities (15–25‰) may have been related to a limitation in QPX's salinity tolerance or have reflected sampling bias (Ragone Calvo et al. 1998). In seasonal collections from one Virginia coastal site, between July, 1996 and June, 1997, Ragone Calvo et al. (1998) observed the

highest prevalences and most severe infections in November and May samples. Smolowitz et al. (1998) reported that quahog mortalities in Massachusetts, associated with QPX infection, were highest in August and October. Temperature and salinity are known to be related to proliferation of other bivalve parasites such as *Perkinsus marinus*, *Haplosporidium costale* and *Haplosporidium nelsoni* (Bower et al. 1994, Ford et al. 1999), thus it is possible that QPX proliferation and pathogenicity may also be influenced by temperature and/or salinity.

Clam harvesting practices may also influence QPX proliferation. Harvesting of quahogs in Atlantic Canada has, traditionally, been done by hand (forks, tongs and rakes), although hydraulic harvesters are also used (Bourne 1989). The population of quahogs in Neguac, N.B., were harvested using an escalator harvester when mortalities started to increase, both in air storage and at Hay Island holding beds, between 1957 and 1959 (Drinnan 1960). Although no clear association between harvest methodology and QPX has been determined, its effect on physiological stress and defense capability seems worth investigating further.

In conclusion, QPX seems to be ubiquitous in both wild and cultured quahogs from the Maritime Provinces and is reported for the first time in quahogs from the Bay of Fundy. In light of past mortalities associated with this parasite, especially in hatchery broodstock being conditioned for spawning, QPX may present a significant challenge to development of quahog aquaculture in our region. The dynamics of infection and pathogenicity under different holding and handling conditions require more investigation to manage pathogen proliferation. This is especially important as uninfected populations seem to be few, if any, in Atlantic Canada, making selection of QPX-free broodstock an impractical solution.

ACKNOWLEDGMENTS

We wish to thank Dr. S.M.C. Robinson, J. Martin, R. Chandler (Dept. Fisheries and Oceans, Canada), E. Semple (Wallace, N.S.), J. and R. Caissie (Caissie Cape, N.B.), B. Murley (New Haven, P.E.I.), P. Burleigh, N. McNair (P.E.I. Dept. Fisheries and Environment) and D. Methé (N.B. Dept. of Fisheries and Aquaculture) for their assistance with collections. Dr. B.A. MacDonald (University of New Brunswick, Saint John) and R.E. Drinnan (Musquodoboit Harbour, N.S.) kindly reviewed early draft manuscripts. Mrs. M. Stephenson, Dr. M. Maillet (DFO, Canada) and W. Morris (U.N.B.S.J) provided valuable technical and statistical support. This project was funded in part by the New Brunswick Alternate Shellfish Aquaculture Species Project, part of a Canada/New Brunswick Cooperation Agreement on Economic Diversification.

ABSTRACT Northern quahogs, *Mercenaria mercenaria* (L.), were sampled from four sites in Two Sisters Creek, South Carolina. Shell lengths (SL) were measured and ages estimated from increments in shell sections. Mean SL of individuals collected at the two sites near the mouth of the creek were significantly larger than those collected in the upper reaches of the tidal creek. The back-calculated mean SL, however, were similar among sites within most age classes. Mean ages of individuals near the mouth were significantly older than those from the upper reaches. Differences in the population age structure were also observed among sites. Several factors are explored to explain the upstream pattern of decreasing SL and ages of quahogs in Two Sisters Creek.

KEY WORDS: *Mercenaria*, quahogs, clams, age, size, growth

INTRODUCTION

Commercial densities of northern quahogs, *Mercenaria mercenaria* (L.), occur in small creeks that dissect extensive tidal marshes of South Carolina and Georgia (Anderson et al. 1978, Walker 1987, 1989). Two Sisters Creek, South Carolina, which is representative of this type of habitat, became part of a State Shellfish Ground (SSG-134) in 1986. Reported landings from SSG-134, which also included Ashepoo River, Rock Creek, Atlantic Intracoastal Waterway, and Ashepoo-Coosaw Cut, averaged only 145 bags/year before an exploratory survey of quahog resources in Two Sisters Creek (S.C. Department of Natural Resources, unpubl. data). Resource managers perceived that quahog exploitation was limited before and after Two Sisters Creek became part of SSG-134. The mean (± SD) shell lengths (anterior posterior axis, SL) of quahogs collected during an earlier exploratory survey of May 6, 1987 indicated that individuals sampled from two sites nearer the mouth were larger (88.1 ± 10.37 mm and 87.1 ± 10.30 mm) than those collected from a mid-way site (69.0 ± 14.81 mm) and a site farther up Two Sisters Creek (61.6 ± 19.26 mm). A similar trend was observed in Christmas Creek, Cumberland Island, Georgia, where relatively higher numbers of larger quahogs (i.e., chowders) were found near the creek's mouth than in the upper reaches of the tidal creek (Walker 1987). Differences in quahog size among sampling sites could have resulted either from variations in growth rate or age of the respective populations.

The objectives of this study were to test the null hypotheses that growth rate and age were similar among quahog populations inhabiting four different upstream sites in Two Sisters Creek, South Carolina (Fig. 1). Age estimations, based on annual growth increments within the shell (e.g., Arnold et al. 1991, Jones et al. 1990, Peterson et al. 1985), were used to compare age and SL of different-aged quahogs from the four sample sites in Two Sisters Creek.

MATERIALS AND METHODS

Study Sites

Quahogs were sampled from four sites within Two Sisters Creek, South Carolina, on February 25, 1994. The site closest to the mouth was designated site 1, and sites 2, 3, and 4 were located progressively farther up the tidal creek (Fig. 1). Midchannel depths of the four sites at flood tide were 7.60 m, 8.20 m, 4.30 m, and 3.35 m, respectively. Tidal range was about 2 m. Bottom water temperatures and salinities at the time of collection ranged from 12 to 14 °C and 21 to 25 gl^{-1}. An estimate of bottom types indicated that sites 1, 2, and 3 were a mixture of mud, sand, and shell; whereas, site 4, although similar, seemed to contain more clay.

Sampling

Quahogs were collected at flood tide from subtidal sites with a hydraulic escalator harvester configured with a Maryland-type head. The mesh size of the escalator conveyor would retain quahogs >32 mm SL if not covered by mud or shell. In this event, smaller quahogs would be harvested. Subtidal bottoms at depths of 2–8 m were sampled across the width of the creek. Sampling at each site continued until sample sizes were ≥ 100 individuals. Quahogs were returned to Clemson University and frozen until analysis. Shell length and height (lateral axis, SH) were measured with calipers to the nearest 0.1 mm. After measuring, individuals were categorized according to the following commercial size groups: sublegals, < 44.4 mm SL; littlenecks, 44.4–67.9 mm SL; cherrystones, 68–78 mm SL; and chowders > 78 mm SL. A subsample of 50 quahogs per site, representative of the distribution at that site, was used for aging.

Age Determination

Quahogs were shucked, and the better valve was selected for sectioning. The valve of larger shells was cut from the ventral margin through the umbo, with a high-speed geological saw mounted with a diamond blade. Smaller shells were embedded in resin epoxy to avoid fracture during the sectioning (Kennish et al. 1980). Similarly, embedded shells were cut with a slow-speed saw mounted with a high-density diamond blade. Valves were polished with various grit carborundum papers and then etched in 1% hydrochloric acid. Age was obtained by counting translucent (dark) bands on the polished surface of a cut valve. Bands were counted

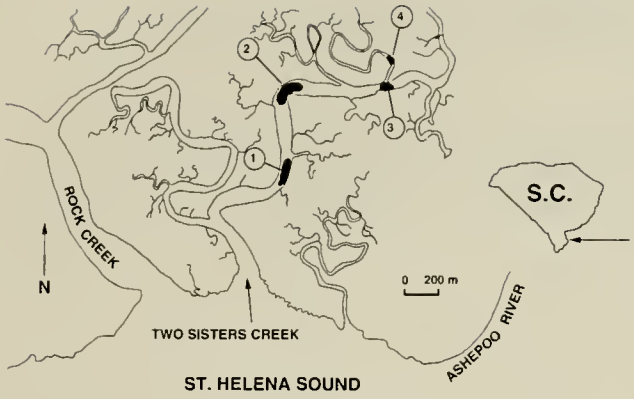

Figure 1. Sampling sites in Two Sisters Creek, South Carolina.

three times with two blind counts by the same observer. Values difficult to read were then washed and exposed to acetone before pressing against an acetate sheet (Kennish et al. 1980, Ropes 1984). The age of these clams was obtained by counting bands using a microfilm projector. A pattern of alternating translucent (dark) and opaque (light) increments on sectioned valves of known aged quahogs cultured in South Carolina waters was used to verify the formation of annual shell growth increments in the study (Devillers 1994).

Back-Calculated Shell Length

Shell heights from the umbo to the translucent increment for each age increment in the sectioned valves of shells were measured to the nearest 0.1 mm (see Jones et al. 1990). Measurements were limited to the first 12 increments, because of the difficulty associated with correctly measuring small increments thereafter. These measurements were then converted to SL using the equation (Eversole, unpubl. data):

$$\ln SL = 1.0493 \ln SH - 0.0136; r^2 = 0.997, n = 1{,}171.$$

Statistical Procedures

Analysis of variance (ANOVA) was used to determine significant differences in SL between the field sample and subsamples. Significant differences in age, SL, and back-calculated SL were also determined by ANOVA. Paired means were compared with the least significant difference (SAS 1985). Alpha level was set at 0.05 for these analyses.

RESULTS

Shell Lengths

Mean SL of the quahogs sampled from sites 1 and 2 were similar but significantly ($P \leq 0.05$) larger than those animals sampled at sites 3 and 4 (Table 1). Individuals from site 3 were also significantly larger than those quahogs sampled at site 4. The mean SL and ranges of these quahogs used for age determination were similar to that observed in the field sample (Table 1).

The frequency distributions of commercial quahog sizes collected from the four sites are presented in Figure 2. Chowders dominated the collections at site 1 (94.2%), site 2 (96.2%), and site 3 (69.8%). Site 4 contained 37.8% littlenecks and similar percentage of cherrystones (26.5%) and chowders (27.8%). Only 1.0%, 1.9%, 8.5%, and 7.9% of the quahogs were sublegal size (< 44.4 mm SL) in collections from sites 1, 2, 3, and 4, respectively.

TABLE 1.

Mean (± SD) and range (in parenthesis) of the shell lengths (mm) of *Mercenaria mercenaria* from four sites in Two Sisters Creek, South Carolina. Values in a column not sharing the same letter superscript are significantly different at $P \leq 0.05$. There was no significant difference between field and subsample mean SL.

	Field Sample		Subsample	
Site	N	Shell Length	N	Shell Length
1	104	93.27 ± 11.23[a] (41.9–110.7)	50	93.08 ± 12.68[a] (41.9–110.7)
2	104	94.27 ± 11.60[a] (36.0–117.5)	50	94.10 ± 11.32[a] (37.7–108.8)
3	106	79.05 ± 17.57[b] (32.2–101.9)	50	78.39 ± 17.81[b] (32.2–100.6)
4	151	67.84 ± 14.32[c] (33.2–97.6)	50	67.92 ± 14.59[c] (33.2–93.5)

[1] Site 1 was closest to the mouth while sites 2, 3 and 4 were progressively farther upstream in Two Sisters Creek.

Age

The oldest age of the sampled quahogs was 29 years from site 1, and the youngest was 1 year from sites 2 and 4 (Fig. 3). Significant differences ($P \leq 0.05$) were detected among the four sites in the average age of quahogs. Individuals on average (± SD) from site 2 (16.7 ± 4.70 years) were older than animals from site 1 (14.9 ± 5.37 years) and in turn, quahogs from site 3 (8.4 ± 3.96 years) and site 4 (4.7 ± 2.30 years) differed from each other and were significantly younger than those from sites 1 and 2. The range of ages in the sample from site 1 was 28 years with several (n = 10) unrepresented age classes in the distribution (Fig. 3). The distribution of ages from site 2 was similar (range and number of missing age classes) but differed from site 1 in having an obvious dominant age class at 15 years. The range of ages from site 3

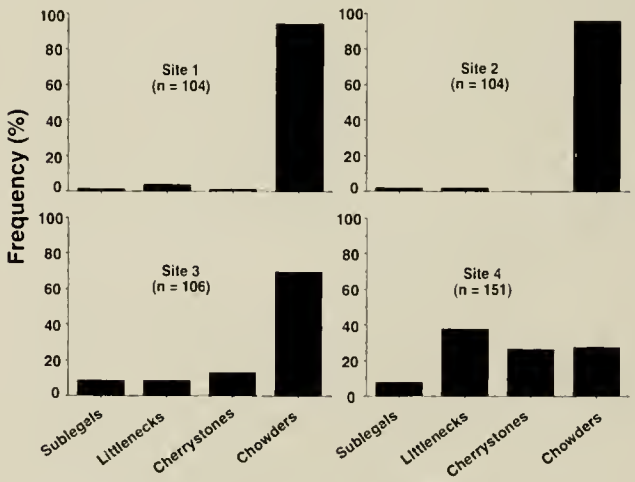

Figure 2. Relative frequency of commercial sizes of *Mercenaria mercenaria* from four sampling sites in Two Sisters Creek, South Carolina. Commercial sizes were sublegals (< 44.4 mm SL), littlenecks (44.4–67.9 mm SL), cherrystones (68–78 mm SL) and chowders (> 78 mm SL).

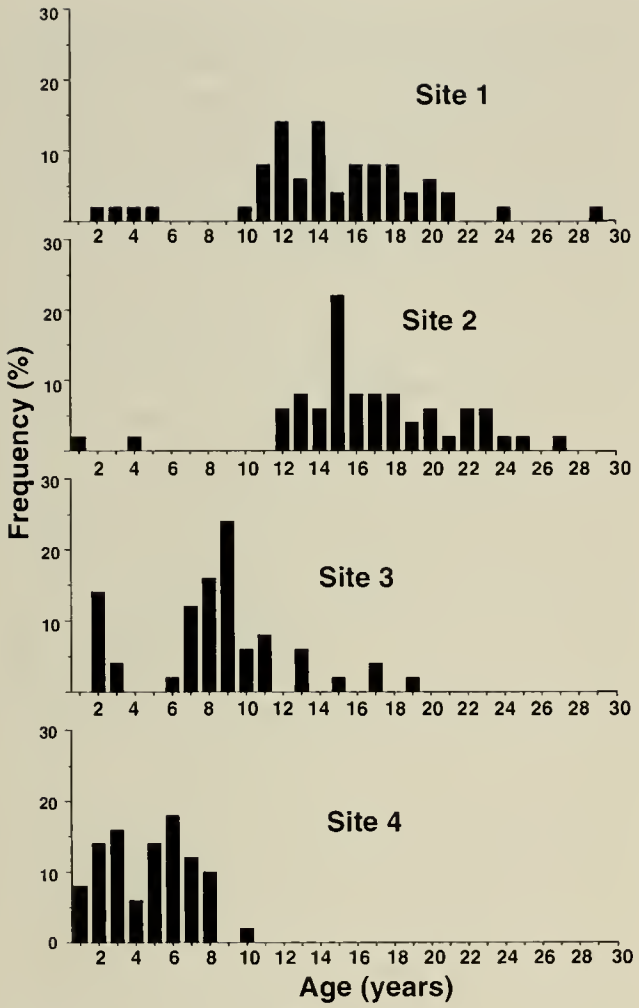

Figure 3. Age structure of 50 *Mercenaria mercenaria* collected from each of four sites in Two Sisters Creek, South Carolina.

encompassed 18 years with six missing age classes; whereas, those animals aged from site 4 spanned 10 years with only one missing age class at 9 years. None of the quahogs sampled from site 4 were older than 10 years; whereas, 90%, 96% ,and 22% of quahogs from sites 1, 2, and 3 were older than 10 years of age.

Back-Calculated Shell Lengths

The back-calculated mean SL of quahogs from sites 1, 2, and 3 were similar in size from age 1 through 11 years (Table 2). One significant difference among the four sites occurred from ages 1 to 4 years when quahogs from site 4 were significantly larger ($P \leq 0.05$) than those quahogs from sites 1, 2, and 3. The only other significant size difference in back-calculated SL occurred at 12 years (Table 2). Quahogs reached reproductive size (35 mm SL, Eversole in press) between 1 and 2 years and commercial size (44.4 mm SL) between 2 and 3 years.

DISCUSSION

Comparison of quahog sizes between this and other studies needs to be done with caution because of different sampling gear efficiencies and the common problem of the under representation of small individuals in samples (Fegley, in press). Although Walker (1987, 1989) used a different collection method, he did collect a similar range of sizes as those collected in this study and observed that chowders (> 78 mm SL) were the dominant commercial size class in 43% of the 40 sites sampled in Georgia waters. He also determined that chowders were more abundant in areas with little or no harvesting; whereas, littlenecks were more abundant in heavily fished areas. In a statewide survey of quahog habitat, littlenecks were found to be the most abundant commercial size class in South Carolina, which has a viable fishery (Anderson et al. 1978). In Two Sisters Creek, which has not been extensively harvested, the dominant commercial size was the chowder in three of the four sites sampled. Greene and Becker (1978), Malinowski (1985), Rice et al. (1989), and Walker (1989) have suggested that the gear used to harvest quahogs is biased towards the larger sizes resulting in differential removal of larger individuals and a shift in the population structure toward smaller commercial sizes. Conversely, it is anticipated that the larger commercial sizes would

[1] Site 1 was closest to the mouth while sites 2, 3 and 4 were progressively farther upstream in Two Sisters Creek.

accumulate in areas not heavily harvested. This accumulation may explain why sites 1 through 3 in Two Sisters Creek were dominated by chowders (Fig. 2), but it does not adequately explain the dominance of littlenecks at site 4, which would be the least likely of the four sites to be commercially harvested or poached because of its size and location. In addition to the affect of harvesting, size and age structure of populations are also influenced by growth rates, recruitment, and mortality (Cerrato 1980). Because quahogs at site 4 grew at the same rate or faster than the quahogs at the other three sites, different growth rates can not solely be used as an alternative hypothesis for explaining differences in sizes among sampling sites.

Annual cycles of shell growth increment formation have been observed in shells of quahogs sampled from Rhode Island to Florida (Arnold et al. 1991, Fritz and Haven 1983, Jones et al. 1989, 1990, Kennish 1978, Peterson et al. 1985) and from South Carolina (Devillers 1994). Mean age determined from sectioned shells revealed that animals sampled from the sites nearest the mouth of Two Sisters Creek were significantly older than individuals collected from site 4 in the upper reaches of the tidal creek. Collections from sites 1 and 2 closest to the mouth also contained the oldest quahogs and the widest spread of ages. Differences in mean age and age frequency distribution among the sampling sites could have resulted from sampling error (e.g., small and under representative samples); however, on two separate sampling occasions and using the same gear, quahog size (age) decreased from sites near the mouth to upstream sites in Two Sisters Creek. If sampling error occurred, it was similar among sites and sampling occasions.

The absence of quahogs older than 10 years in the collection from site 4 may have been the consequence of a catastrophic event, intense predation or the recent successful establishment of the population. Low salinity periods resulting from hurricanes are reported to cause extensive quahog mortalities (Wells 1961). Although site 4 is more likely to be influenced by a catastrophic event than the other three sampling sites because of its smaller size, we have no evidence to indicate such an event occurred in this section of the coast 10 years ago. Furthermore, it is unlikely that such a large-scale event would have a stratified effect over such a restricted area as from site 1 to site 4.

The subject of settlement and postsettlement roles in defining macroinvertebrate soft-sediment communities has been extensively reviewed by Butman (1987), Olafsson et al. (1994), and Snelgrove and Butman (1994). Although these authors discuss several factors important in defining adult assemblages in soft sediments, it has not been clearly established whether adult spatial patterns result from differential larval settlement, differential postlarval survival, or redistribution (Armonies 1996, Bachelet et al. 1992, Peterson 1986, Wilson 1990).

Existing data indicate that hydrodynamic processes play a major role in determining the settlement of bivalves in soft marine sediments (e.g., see the review by Butman 1987). Near-bottom hydrodynamic forces determine the fate and flux of bivalve larvae over a patch of bottom. These forces are particularly important in the case with *M. mercenaria* larvae because of their weak swimming ability (Bachelet et al. 1992). *M. mercenaria* exhibited passive settlement when exposed to different sediment types in still and flume-flow water tests (Butman 1987, Butman et al. 1988).

Field studies evaluating the importance of hydrodynamics to recruitment are few (e.g., Carriker 1961, Mitchell 1974, Petersen 1986, Pratt 1953, Wilson 1990). Pratt (1953) provided the earliest suggestion that the distribution of quahogs was similar to the sediment particles in Narragansett Bay, Rhode Island, implying hydrodynamic processes were important in quahog distribution. He concluded from measurements of current patterns that early stage larvae coincided with the dense assemblages of adults and that hydrographic processes mixed and transported the larvae with time to potential settlement sites. Carriker (1961) commented that the most striking feature of the horizontal distribution of larvae in Little Egg Harbor, New Jersey, was its unevenness and as a consequence, quahogs set in areas that did not have adults. After studying quahog abundance and distribution in Southampton Waters, England, Mitchell (1974) came to a similar conclusion that the distribution of adult quahogs is in part controlled by tidal transport of the larvae produced by spawning beds. Mitchell (1974) also hypothesizes that variation in recruitment among years in different sites in Southampton Waters was related to the successful transport and settlement of competent larvae.

Andrews (1983) observed that most of the oyster larvae carried upriver during flood tide were transported down river during ebb tide with the exception of those few oyster larvae trapped upriver in oyster beds and small tidal creeks of James River, Virginia. Andrews (1983) also postulated that upriver entrainment was more successful in systems with low flushing rates than highly flushed systems. The four sites in Two Sisters Creek, because of their channel width and depth, have different flushing rates, with site 4 having the highest projected rate of the sites sampled. Quahog larvae produced in the main body of Two Sisters Creek probably could have been entrained in a tidal excursion at site 4. However, considering the patchy distribution of larval quahogs and the short window competent larvae have to set at slack tide (Carriker 1961, Armonies 1996), the probability of setting before being flushed from the small tidal creek was probably low. If entering and setting larvae survived predation pressures, perhaps a resident population of quahogs would have been established and served as a source of larvae for future recruitment at site 4. Because quahogs have a tendency to spawn at ebb slack water and be transported upstream with the subsequent flood tide (Carriker 1961), larvae from an established population at site 4 would have an increased probability of being retained in the tidal creek and recruiting to the population.

Another explanation for the different age distributions of quahogs in Two Sisters Creek involves the resuspension and distribution of postlarval individuals. Shifts from the initial distribution of recently settled *Macoma balthica* have been observed in the Wadden Sea (Armonies and Hellwig-Armonies 1992). Although postlarval *M. mercenaria* possess a temporary byssus thread (Carriker 1961), it can be released or broken resulting in dislodgment and resuspension by water flow (Butman et al. 1988). Resettlement of postlarval quahogs at site 4 in Two Sisters Creek would also require the appropriate hydrodynamic forces for transport and the subsequent survival of post larvae.

Predation helps shape quahog population structure (Bricelj 1993) by selecting the smaller (younger) more vulnerable individuals in the population (Whetstone and Eversole 1978, 1981). Of the suite of predators consuming quahogs (Gibbons and Blogoslawski 1989), crabs are the most important predators in South Carolina (Whetstone and Eversole 1978). Crab-related mortalities up to 100% were observed in juvenile quahogs planted in unprotected sites in Georgia and Florida (Menzel and Sims 1962, Godwin 1968). Quahog survival is improved if small individuals are provided some protection or if predators are removed (Eldridge et al. 1979, Peterson 1982). Greene and Becker (1978) observed an increase in quahog recruitment after a severe winter reduced the

number of blue crabs in Great South Bay, New York. Peterson (1982) demonstrated that the roots and rhizomes of seagrasses provide protection for infaunal species such as quahogs from some predators. Both Peterson (1982) and Wilson (1990) concluded that as much as 50% of the difference in quahog density between vegetated and unvegetated areas was attributable to enhanced post-larval survival. There is adequate information to indicate that post-settlement processes (predation) play an important role in invertebrate populations in soft marine sediments (see Olafsson et al. 1994 review). Although the distribution and abundance of predators within Two Sisters Creek could have played a role in the age distribution of quahogs among the four sites, we have no evidence to indicate predators either eradicated all the quahog sets 11+ years ago or selectively preyed on the older, larger individuals in site 4.

The maximum ages of quahogs are lower in faster-growing populations in southern latitudes along the United States coast than those observed in the slower-growing, more northerly populations of quahogs (Ansell 1968, Jones et al. 1990). Fewer quahogs would be expected to attain an older maximum age in site 4 if the faster-growing individuals at this site died at a younger age than at the other sites. Differential mortality of the faster-growing quahogs also helps explain why fewer chowders were observed in site 4 than in the other sites.

Our results illustrate that the differences in quahog sizes among sampling sites in Two Sisters Creek was attributable to different age structures at the four sites. Quahogs collected from the upper reaches of tidal creek (site 4) were younger than those collected downstream, and none of the quahogs from site 4 was older than 10 years; whereas, the oldest quahogs from sites 1, 2, and 3 were 29, 27, and 19, respectively. Although the first steps in establishing a population of quahogs involves settlement, the importance of hydrodynamic processes or predation (mortality) effects on post-larvae cannot be underestimated. Unfortunately, we have very little data to support a hypothesis to explain the observed age distribution in Two Sisters Creek. Future efforts to investigate quahogs recruitment should include an integrated approach that simultaneously considers factors such as hydrodynamic processes and post-settlement survival. Unraveling these causes of recruitment variation will be crucial to understanding the distribution and abundance of quahogs.

ABSTRACT In Washington State, target fishing mortality rates (F) for the geoduck clam, *Panopea abrupta* (Conrad, 1849), are based on relative changes in biomass and therefore depend on growth patterns. With these policies, higher growth rates lead to larger harvest quotas so that applying higher rates to areas with slower growth would cause overharvesting. Therefore, in estimating growth patterns, it is important to recognize the scale to which estimates of growth rates should be applied. In this study, we tested whether growth parameters differed among regions and among local sites within regions in Washington, and whether they differed enough to compel managers to create location-specific policies. Von Bertalanffy growth parameters were estimated for 11 sites dispersed among four regions. Among those sites, L_∞ ranged from 13.2 to 17.3 cm, k ranged from 0.113 to 0.235, and t_0 ranged from −0.029 to 0.806. Of the three parameters, the growth constant k had far more influence on target fishing mortality rates (F) than either L_∞ or t_0. Statistically significant differences in k were found among all local sites within geographic regions. However, only some of the differences were of a magnitude to concern management policies. We have proposed a general method for calculating and then testing for managerial significance when a linear relationship exists between k and the fishing mortality rate (F). Our results implied that managerially significant differences in k existed among local sites within Washington's geoduck management regions, posing a dilemma for managers who, by convention, propose a single target fishing mortality rate for each region.

INTRODUCTION

The Pacific geoduck clam *Panopea abrupta* is a large hiatellid bivalve that occurs from Alaska to Baja, CA, and west to southern Japan (Bernard 1983). Geoducks are one of the largest burrowing clams in the world, reaching a live whole weight of 3.25 kg (Goodwin and Pease 1987). Adults are buried to 1 m in sand and mud substrates from the lower intertidal to depths of more than 110 m (Jamison et al. 1984). They dominate the biomass of benthic infaunal communities in many parts of Puget Sound, WA, where they have supported a commercial dive fishery in subtidal waters since 1970 (Goodwin and Pease 1991). Commercial dive fisheries also exist in Alaska and British Columbia (Campbell et al. 1998), and geoducks now provide the most valuable commercial clam harvest on the Pacific Coast of North America. The average annual ex-vessel value of Washington's geoduck harvest from 1990 to 1998 was US$14 million. From 1971 through 1997 annual landings have averaged 1,540 tons.

The Washington Department of Fish and Wildlife and several of the Washington tribes manage commercial geoduck harvest on a regional basis. There are six regions statewide that are based largely on legally defined tribal fishing boundaries. By coincidence, these boundaries also roughly conform to major oceanographic basins within Puget Sound (Ebbesmeyer et al. 1984). Currently, four of the regions (Fig. 1) are surveyed for biomass, and geoduck quotas are calculated annually for each of these regions as the product of biomass and a target fishing mortality rate. The target fishing mortality rate (F) is based on the output of an age-based equilibrium yield model (Bradbury and Tagart 2000), which relies in part on a three-parameter von Bertalanffy growth function. Past studies on geoduck growth (Goodwin 1976, Breen and Shields 1983, Anderson 1971) have only provided point estimates for annual growth increments, making it impossible to determine whether growth rates differed significantly among geographic areas. In this paper, we first estimated von Bertalanffy growth parameters for individual geoducks at 11 Washington sites and then conducted hypothesis tests for differences in growth parameters within and among the management regions.

In conducting a hypothesis test, statistical significance is not always biologically meaningful. In this study, statistical significance refers to *whether or not* the growth parameters change; biological significance refers to *how much* the growth parameters change. Statistical significance is well defined; however, biological significance is not. In this study, determining biological significance stemmed from the decision processes that were in place for managing the geoduck harvest and thus are more appropriately termed "*managerial significance*." Managerial significance was determined by how much the growth parameters must change before management decisions would be altered, and this degree of change was factored into the hypothesis-testing procedure. We concluded that according to the management criteria given, not only should regional specific growth parameter estimates be used, but within some regions site-specific estimates should also be used.

METHODS

Data

Geoducks were collected from 1979 to 1982 at 11 previously unfished sites in Washington (Fig. 1). The sites were chosen op-

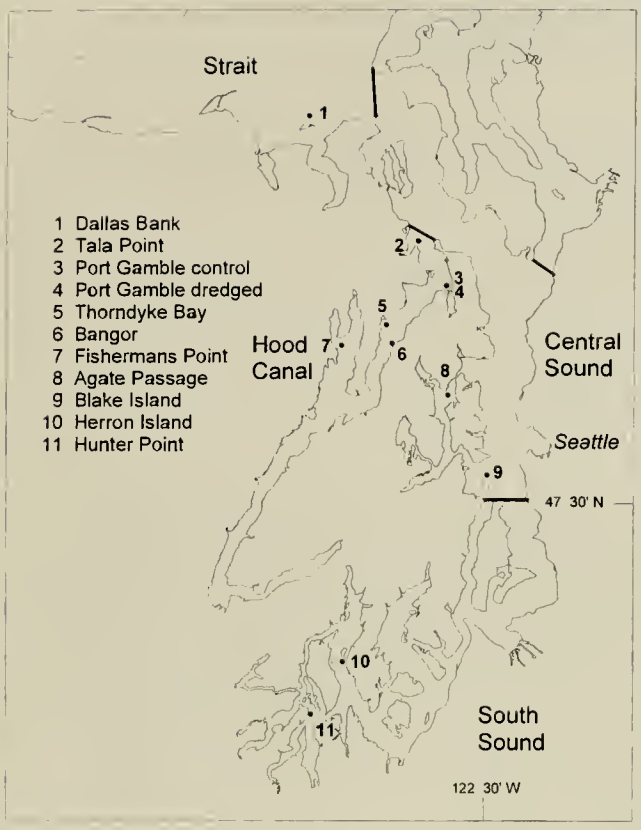

Figure 1. Sampling sites for geoduck growth. Also shown are boundaries for four of Washington's geoduck management regions; the two regions not shown contained no sampling sites and no surveyed geoduck biomass.

portunistically from among those scheduled at the time for prefishing surveys. However, they were spread out over the entire commercial fishing range of Washington geoducks. Preliminary dive surveys were conducted at each of the 11 study sites to map their boundaries. The shallow to deep boundaries of a commercial geoduck tract were set by management to be between 6 and 23 m mean lower low water. The along-shore boundaries of a commercial tract were subjectively defined on the basis of drops in geoduck densities, suitability of substrate, proximity to sewer outfalls or ferry traffic lanes, etc.

Geoducks were sampled from a series of transects. The transects were approximately 0.91 m wide, ran perpendicular to the shore from 6 to 23 m, and were spaced approximately 1 km apart (Fig. 2). In some of the larger sites, transect lines were spaced at systematic intervals wider than 1 km. In each site, the first transect was located opportunistically along the shoreline at one end of the mapped bed. Because the divers were unable to see either the substrate or the geoducks from the survey boat before selecting the starting point, we made the assumption that the selection represented a random starting point.

For logistical purposes, each transect was divided into 45.72-m-long subsections. Divers used a commercial water jet to dig geoducks from the approximate center of selected subsections. They were instructed to dig the first 10 geoducks seen without regard to size or any other criterion. The subsections selected were every fourth one, ignoring transect identity, i.e., as if the transects were laid end to end. For example, if the first two transects were each made up of 10 subsections, then the first, fifth, and ninth

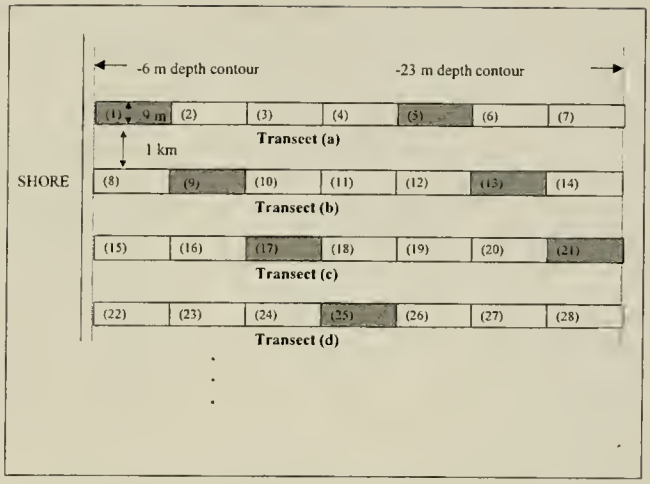

Figure 2. A schematic of the sampling design (not to scale or number). The smaller rectangles represent the hypothetical 46-m-long subjections (1–28) that make up the hypothetical transects (a–d). Ten geoducks were collected from every fourth subsection (shaded) as if the transects had been laid end to end.

subsections of the first transect would have been sampled and the third and seventh subsection of the second transect would have been sampled, etc. This procedure resulted in samples ranging from 21 to 258 geoducks, depending on the size of the site (Table 1).

A total of 1,216 geoducks were sampled from the 11 sites. They were held in saltwater and returned to the laboratory within a few days of collection for processing. All geoducks were numbered and separated by site before processing, and the greatest anterior-posterior length of the right valve was measured with calipers. Thirty geoducks per site were subsampled for this growth analysis. The subsample from each site was drawn randomly from the numbered shell samples, ignoring the subsection identity. Of the 330 sampled, 234 were used in the growth analysis. The 96 geoducks eliminated from the subsample were discarded either because they were unreadable or because they were <15 years old.

Annual growth increments were determined using the acetate-peel method developd by Thompson et al. (1980) and described for geoducks in Shaul and Goodwin (1982). Growth increments for ages beyond 25 years were not calculated, because geoducks reach their asymptotic size between the ages of 15 and 25 years (Shaul and Goodwin 1982). The yearly rings on individual geoducks were measured to provide length at age data for individuals. Thus, in the rth region ($r = 1 \ldots 4$), the data for the ith individual ($i = 1 \ldots n_r$) consisted of paired observations (l_{ijr}, a_{ijr}, $j = 1, \ldots J_{ir}$) where l_{ijr} was the length measured for age ring j and a_{ijr} was the age assigned to age ring j. The number of individuals varied by region and the number of age rings varied by individual (because some geoducks were less than 25 y old). From the paired observations on each individual, length was regressed on age with a nonlinear von Bertalanffy function:

$$l_{ijr} = L_{\infty,ir}(1 - e^{k_{ir}(a_{ijr} - t_{0,ir})}) + \varepsilon_{ijr}$$

where $\varepsilon_{ijr} \sim N(0,\sigma^2_{ir})$. Thus, each nonlinear regression produced a set of estimated parameter values $\{\hat{L}_{\infty,ir}, \hat{k}_{ir}, \hat{t}_{0,ir}\}$ for the ith individual ($i = 1 \ldots n_r$) in the rth region ($r = 1 \ldots 4$). The variance σ^2_{ir} represented both the measurement error and the uncertainty caused by the absence of old growth rings. Therefore, the vari-

ances for older geoducks with more growth rings were likely to be more precise than for younger geoducks. The resulting heteroscedasticity for geoducks >15 years of age was thought to be minimal and was ignored.

Hypothesis Testing

The experimental design was a two-factor analysis of variance (ANOVA) in which the first factor was region and the second was sites nested within regions. We first conducted a hypothesis test on site effects within each region and only conducted a test among regions if the site effects were nonsignificant. In this case, nonsignificance meant not managerially significant. Thus, for all statistically significant tests, Tukey multiple comparisons (Neter et al. 1985) were used to test for managerial significance. The Tukey multiple comparisons yielded confidence intervals for the differences in growth among locations. For any one comparison to be managerially significant, the difference in growth had to be at least some constant c. These comparisons were identified by confidence intervals that excluded the interval $(-c, c)$.

Calculating Managerial Significance ($c = 0.027$)

Most U.S. and Canadian fisheries, including all of those under U.S. federal jurisdiction, are managed using biological reference points (BRPs). BRPs are calculable quantities that describe a population's state and are usually used as targets for optimal fishing (National Research Council 1998). A BRP is most often expressed as a fishing mortality rate (F); examples include F_{MSY}, F_{max}, and $F_{xx\%}$. These are the fishing mortality rates that are expected to achieve, over the long term, maximum sustainable yield, maximum yield per recruit, and a spawning stock biomass that is $xx\%$ of the unfished level, respectively.

We considered two management criteria in calculating the threshold of managerial significance for geoduck growth parameters: (1) the BRP used by managers in setting the target fishing mortality rate and (2) the number of significant digits to which this target fishing mortality rate was calculated. Geoduck managers in Washington currently use as a BRP the fishing mortality rate corresponding to $F_{40\%}$, a reference point that is widely used for U.S. West Coast groundfish (Clark 1993). Managers have agreed to calculate this target fishing mortality rate to three decimal places. For example, there is a managerially significant difference between annual fishing mortality rates of 0.027 and 0.028, but not between 0.027 and 0.0273.

The three von Bertalanffy growth parameters were first evaluated to determine which had the most influence on yield model predictions. The equilibrium model described in Bradbury and Tagart (2000) was used to calculate $F_{40\%}$ for different values of $\{L_\infty, k, t_0\}$ in the range observed in the data. L_∞, while it affected model predictions of absolute yield, did not affect relative spawner-per-recruit biomass or relative yield per recruit and was therefore eliminated from further analysis. Figure 3 shows that the growth parameter k is more influential on $F_{40\%}$ than t_0. Because L_∞ had no impact on $F_{40\%}$ and t_0 had only minimal impact, we conducted univariate hypothesis tests on k.

Changes in k would only affect management decisions if they caused the model-based fishing mortality rate to change by 0.001 or more. In general, whenever a linear relationship exists between k and F with slope β,

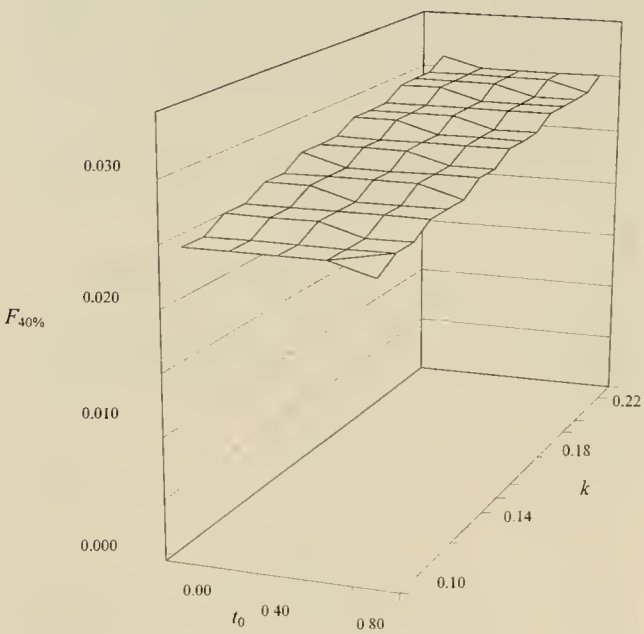

Figure 3. Surface plot of $F_{40\%}$ values as a function of the observed ks and t_0s.

$$\frac{\Delta F_x}{\Delta k} = \beta \Rightarrow \Delta k = \frac{\Delta F_x}{\beta}.$$

In this example, a linear regression of the level of change $F_{30\%}$ on k yielded a highly significant slope ($P < 0.001$) of $\beta = 0.0366$. Using this slope and Washington's management decision to calculate annual fishing mortality rates to three significant digits, $c = 0.001/0.0366 = 0.027$. Thus, absolute differences in k among sites (or regions) ≥ 0.027 were managerially significant.

RESULTS

Table 1 shows the von Bertalanffy parameter estimates and their variances for the 11 study sites. The resulting growth curves for the fastest-growing site (Fishermans Point) and the slowest-growing site (Dallas Bank) are shown in Figure 4; the growth curves for all other sites lie between these two. Also shown for comparison is Anderson's (1971) growth curve for geoducks at Big Beef Creek and Dosewallips beaches in Hood Canal.

Test for Nested Site Effects

The test for site effects within regions was statistically significant ($F_{7,223} = 24.72$, $P = 0^+$) for all regions. Further testing for managerial significance produced mixed results. The Tukey multiple comparisons between sites within regions showed four comparisons in which the differences were managerially significant (Table 2): between the sites in the South Sound region and among several sites in the Hood Canal region.

Power of Tukey Multiple Comparisons

Because the null hypothesis of the growth parameters not being significantly different was not rejected for sites within Hood Canal and for the two sites in the Central Sound region, we conducted a power analysis to assess whether or not the nonrejection was meaningful. The power analysis estimated the probability that any one of the Tukey multiple comparisons would have excluded the interval (−0.027, 0.027) if in fact the differences in k among sites had been at least 0.027. To estimate this probability, we used the two-sample t-test power analysis option of Power Analysis and Sample Size (PASS version 6.0, Hintze, 1996). Each of the multiple comparisons was a t-test that needed a Tukey multiplier. To adapt the software into giving the appropriate power estimates (Table 3), we inflated the estimated standard deviation of the comparison, ($\sqrt{MSE} = 0.0309$, calculated by the ANOVA) by the ratio of the Tukey multiplier (3.217) to the analogous Z multiplier (1.96):

$$\sqrt{MSE}_{\text{inflated}} = 3.217/1.96\sqrt{MSE} = 1.64\sqrt{MSE} = 0.0507.$$

Power in the Hood Canal Region

In the Hood Canal region, there were 6 sites and 15 comparisons, 3 of which were significant. With an average sample size of 22, the estimated probability was 0.4233 (Table 3) for detecting a 0.027 difference in any one of the comparisons. If the actual differences in k among sites had been at least 0.027, then one would expect to detect more than three of them. In fact, the probability of detecting a difference of 0.027 in at most three comparisons, where the probability of detection was 0.4233 per comparison, is the probability that a binomial random variable with $N = 15$ and $P = 0.4233$ was less than or equal to 3. This probability was 0.0645. Given that this probability was very low, there is evidence that among the sites in Hood Canal, other than Fishermans Point, the differences in k are not likely to be greater than 0.027 and thus need not be estimated separately.

Power in the Central Sound Region

In the Central Sound region, there were two sites, and the comparison was not significant. With a power of 0.4233 of detecting significance in a comparison, the chance of not rejecting the null hypothesis was $1 - 0.4233 = 0.5767$. Because this probability is high, nonrejection of the null hypothesis was not meaningful; i.e., the results are inconclusive.

Because Hood Canal was the only region producing evidence for common growth rates among sites, we did not pursue a test of regional differences. Thus, we recommend that with the given management criteria, separate growth models should be used in the regions given in Table 4. For the sites within Hood Canal other than Fishermans Point, the average growth parameter was calculated as the mean of the average growth parameters in each site (Table 4).

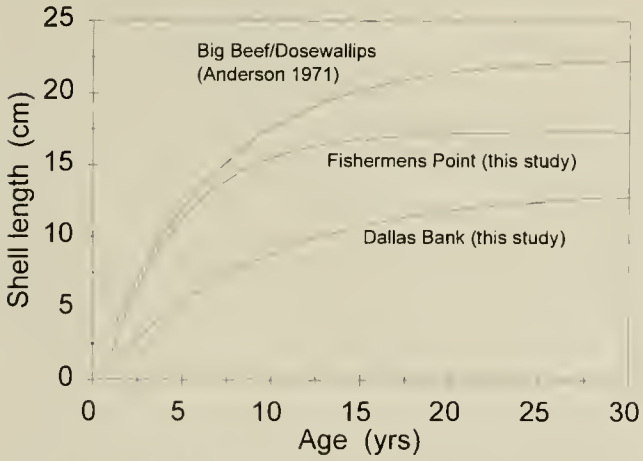

Figure 4. The von Bertalanffy growth curves for geoduck growth at the fastest growth site (Fishermans Point) and the slowest growth site (Dallas Bank) in this study. Also shown is Anderson's (1971) growth curve for Big Beef/Dosewallips.

DISCUSSION

The first result to note is the difference in the growth curves presented here and that from Anderson (1971). We estimated both a lower rate of growth (k) and a smaller asymptotic size (L_∞) for geoducks; however, differences in the target population explain this discrepancy. Anderson's target population consisted of subtidal and intertidal geoducks between the presumed ages of 1 and 5 years. Our target population consisted of subtidal geoducks older than 15 years. Because mean geoduck shell length is inversely proportional to water depth (Goodwin and Pease 1991), it is expected that Anderson's sample would have a higher estimate of L_∞. Likewise, a higher estimate of k is expected with a younger target population.

Of the three von Bertalanffy growth parameters, only one was determined to be influential: the parameter k. For the criteria given, managerial significance was calculated to be differences in k of 0.027 or greater among locations. That is, if the growth parameter differed by more than 0.027 among locations, then location-specific growth estimates should be used for setting harvest quotas.

Data that were collected in four different regions encompassing

* The confidence intervals were calculated using a Tukey multiplier of 3.217, i.e., $\Delta \pm 3.217 * SD(\Delta)$. The multiplier corresponded to a studentized range distribution 95th% quantile with 11 and ∞ degrees of freedom.
† Statistically significant data in these rows.

11 different sites were tested for differences among growth parameters. Statistically significant differences in k were detected among most of the sites within the three regions Central Sound, Hood Canal, and South Sound. Further testing showed that in the South Sound, the sites were also significantly different. In Hood Canal, only one site was significantly different from the others. In the Central Sound, the results were inconclusive. Therefore, to preserve the management sensitivity criterion of 0.001 in the estimated $F_{40\%}$ levels, we recommend different growth parameter estimates be used for each site in Straight, Central Sound, and South Sound and that one common model for the sites in Hood Canal other than Fishermans Point be used.

We speculate that environmental factors related to tidal flow may have been a primary cause of the differential growth rates. Goodwin and Pease (1991) found that the average shell length of geoducks in Puget Sound was greatest in sandy substrates and decreased in both muddier substrates and those composed of pea gravel. Because size and growth are related, it is reasonable to conclude that growth is greatest in sites that are subject to intermediate tidal flow (i.e., those composed primarily of sand) and decreases in both low-energy (muddy) and high-energy (gravelly) environments. The substrate was primarily composed of sand at the three sites in our study with the highest k values (Fishermans Point, Hunter Point, and Agate Passage). The three sites with the lowest k values were Dallas Bank, a site composed primarily of pea gravel, and Tala Point and Thorndyke Bay, both of which are muddy. Goodwin and Pease (1991) also suggested relationships betwen geoduck size and environmental factors such as primary productivity and water temperature. Along with tidal currents, these factors are likely to vary from site to site, resulting in differential growth parameters.

Evidence for site-specific growth differences poses a dilemma for managers who must recommend a single regional harvest rate. If growth rates were common among sites, a regional estimate based on any selection of sites would be unbiased. However, we found that the growth constant can be site specific, requiring ad-

justments to a sampling plan for estimating an unbiased regional parameter. Because the sites in this study were not selected at random, a regional k that is an average of the estimated site ks will be biased. Managers might consider using the lowest estimated k-value with the expectation that that would be a conservative approach. Alternatively, another study could be conducted using a sampling plan designed to yield unbiased regional estimators.

ABSTRACT The natural mortality rate of geoduck clams, *Panopea abrupta* (Conrad, 1849), was estimated from data collected at 14 previously unfished sites in Washington State in order to predict the potential yield of the commercial fishery under various harvest rate strategies. The instantaneous rate of natural mortality (M) estimated by the catch curve method for geoducks of ages 28–98 was 0.0226 y^{-1}. Other important life history parameters—growth, schedules of sexual maturity, weight-at-age, and fishery selectivity—were estimated from the literature and file data. These parameter estimates were used to drive an age-based equilibrium yield model that predicted yield per recruit (YPR) and spawning biomass per recruit (SPR) over a range of fishing mortality rates. The model produced values of the instantaneous fishing mortality rate (F) for five commonly used constant harvest rate strategies. The fishing mortality rate producing maximum YPR (F_{max}) ranged from 0.053–0.100 depending on the site growth parameters, but reduced SPR to 15–21% of the unfished level. F-values for the $F_{0.1}$ strategy ranged from 0.28 to 0.37, reducing SPR to 35–37% of the unfished level. Three harvest rate strategies that reduce SPR to either 35%, 40%, or 50% of the unfished level were also evaluated, with F-values ranging from 0.018 to 0.036. The $F_{40\%}$ strategy, currently adopted by Washington managers, was achieved with $F = 0.028$ (averaged over all sites), corresponding to an annual harvest rate of 2.7% of the exploitable biomass. The model was most sensitive to estimates of M, whereas growth, fishery selectivity, and sexual maturity schedules had relatively little effect on yield or SPR. Apparent shifts in recruitment during the past 30–45 y may have biased the estimate of M. Direct estimates of M and recruitment are therefore a high research priority if the model outputs are to remain useful.

KEY WORDS: Geoduck, *Panopea abrupta*, natural mortality, yield, harvest rate, spawning biomass

INTRODUCTION

The geoduck clam *Panopea abrupta* (Conrad, 1849) supports the most economically important clam fishery on the Pacific Coast of North America (Campbell et al. 1998, Hoffmann et al. 2000). Since 1967, the Washington Department of Fish and Wildlife has performed annual dive surveys to estimate the exploitable biomass of geoducks in Washington. "Exploitable biomass" here refers only to geoducks within the legally fishable water depths of 6–23 m, in areas that are not polluted or otherwise unsuitable for commercial fishing and of sufficient size for their siphons to be visible to divers. Based on market and survey samples in Washington, this excludes most geoducks <300 g. Of 11,181 geoducks randomly sampled using commercial methods, only 2% were <300 g (Goodwin and Pease 1987). Geoducks usually attain this size in 5–7 y (Hoffmann et al. 2000).

Exploitable geoduck biomass on a commercial bed is estimated as the product of the total bed area, the mean weight per geoduck, and the mean density of geoducks. Mean density is estimated by counting geoduck siphon "shows" using a systematic strip transect technique (Goodwin 1978). Mean weight per geoduck is estimated from a series of samples dug at systematic intervals along the transect lines. The sum of the most recent biomass estimates on all surveyed beds within a management region constitutes the regional biomass estimate. There are currently six geoduck management regions in Washington, based largely on legally defined tribal fishing boundaries. Because only a few beds can be surveyed intensively in this manner each year, regional biomass estimates consist of the most recent estimate for each bed, with known catches subtracted from those beds as they are fished.

To establish annual fishing quotas, managers apply a target harvest rate to the exploitable biomass estimate in each management region. Beginning in 1981, the target harvest rate was fixed at 2% of the estimated virgin (unfished) biomass on surveyed, commercially viable beds. This target harvest rate was based on a Ricker (1975) yield per recruit (YPR) model, but the model outputs were never explicitly documented. Furthermore, emphasis in fisheries management has shifted since that time; harvest strategies based on YPR analyses (e.g., F_{max} and $F_{0.1}$) are now often supplanted by strategies that seek instead to preserve the reproductive potential of the population. These spawning biomass per recruit (SPR) strategies are increasingly being used in marine finfisheries (Clark 1991) and to a lesser extent in shellfisheries (Quinn and Szarzi 1993).

In this study, we derive estimates of the natural mortality rate (M) from geoducks sampled at previously unfished sites in Puget Sound and the Strait of Juan de Fuca. We also construct schedules of sexual maturity, weight-at-age, and fishery selectivity from the literature and file data. We use these estimates to drive an age-based equilibrium yield model that predicts YPR and SPR over a range of fishing mortality rates. We also explore the limitations of the model and conduct sensitivity tests to determine which parameters most influence the model's predictions. Finally, we use this information to recommend research aimed at refining the most important parameter estimates.

METHODS

Sampling Sites and Procedures

Geoducks were sampled between 1979 and 1981 at 14 previously unharvested sites in Puget Sound and the Strait of Juan de

Fuca to obtain information on age distribution (Fig. 1). The sites span four of the current six management regions, with six sites in the Hood Canal region, two sites in the Central Sound region, one site in the Strait region, and two sites in the South Sound region. Samples were taken randomly within each site at depths of 10–20 m by washing geoducks from the substrate with a commercial water jet. Age was determined from annual growth increments in the hinge plate using the acetate-peel method (Shaul and Goodwin 1982).

The instantaneous rate of natural mortality (M) was estimated from the geoduck age-frequency distribution using two different catch curve models (Robson and Chapman 1961, Ricker 1975). Both models assume that mortality is constant for all ages used in the catch curve. The Robson and Chapman model is based on a geometric distribution and assumes that year-class survival and recruitment are constant and all ages are equally selected. Geoducks are extremely long-lived, so that the number of animals observed in each 1-y age class is typically low, even for sample sizes in which $n > 1{,}000$. Despite this problem, we chose to preserve the data in 1-y age classes rather than aggregating ages, a procedure that potentially ignores real variability in the original data and may slightly inflate estimates of M (Noakes 1992). It was not possible to estimate site-by-site mortality rates, because no individual site contained enough data to construct reliable catch curves. Age frequencies were therefore pooled from all 14 sites in order to create the catch curve.

To avoid arbitrary choices of the upper and lower ages used in the catch curve "right limb," we established a protocol for data inclusion: The initial upper age limit for the catch curve was the first age at which our sample contained no geoducks (i.e., the first gap in frequency). We then excluded younger age frequencies if they were identified as outliers by Weisberg's (1985) outlier test. Two methods were used to select the lower age limit for the catch curve: (1) The Chi-square procedure described in Robson and Chapman (1961) was used to differentiate partially selected ages, and (2) catch curve regressions were calculated for all possible lower age limits, and we used an *ad hoc* procedure to optimize the coefficient of determination (r^2) and the linearity of positive and negative residuals plotted against age. Once the lower and upper age limits for the catch curve were identified, a Chi-square formula was then used to test goodness of fit of fully selected ages to a geometric distribution (i.e., the Robson and Chapman model). The von Bertalanffy growth parameters estimated at 11 Washington sites from Hoffmann et al. (2000) were used as site-specific growth inputs. Sexual maturity, weight-at-length, and fishery selectivity parameters were derived on the basis of published literature from Washington and British Columbia.

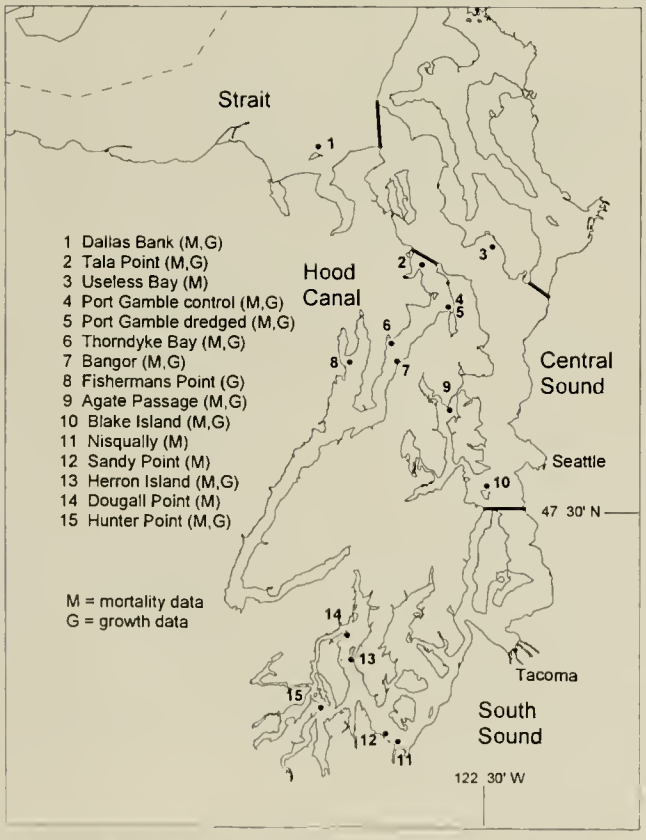

Figure 1. Sampling sites for geoduck natural mortality and growth. Also shown are boundaries for four of Washington's geoduck management regions; the two not shown contained no sampling sites and no surveyed geoduck biomass.

Yield Model

Geoduck yield was modeled using a deterministic, age-structured equilibrium yield model. Given a set of parameter estimates for mortality, maturity, growth, and selectivity, the model collapses the number of geoducks at age for all cohorts in the population to a single cohort, assumed to represent the stable age distribution of the population. Population size was based on an initial unfished spawning population, by a declining exponential function for survival at age, and by the Baranov catch equation (Ricker 1975). Baranov's catch equation says that annual catch is a simple linear function of instantaneous fishing mortality and mean population size. The derivation of Baranov's catch equation is presented in Seber (1982). Seber cites Baranov (1918) as the origin of the catch equation, hence its common name. The model assumed continuous recruitment, the magnitude of which was based on a Beverton-Holt stock-recruitment relationship (Ricker 1975). The Beverton-Holt stock-recruitment relationship, commonly used with marine fish, is an asymptotic function that estimates annual recruitment based on parent stock size. The implication of this relationship is that over a broad range of parent stock size, recruitment is stable, but as parent stocks reach critically low levels, recruitment drops precipitously. A maximum age (a_{max}) in the model served as an "accumulator age" category that encompassed all ages $a \geq a_{max}$. The assumption implicit in this formulation is that no significant changes in growth, weight, maturity, or selectivity occurred beyond a_{max}. In the case of geoducks, this assumption was reasonable and is addressed below. For other applications, the model could be simply extended to accommodate an unlimited number of older age classes. The model was constructed as a QuattroPro for Windows (version 5.0) spreadsheet.

Table 1 lists the user-supplied inputs required by the model. These include estimates of the natural mortality rate, the growth rate, the stock-recruit (S-R) relationship, the unfished spawning biomass, fishery selectivity, sexual maturity, and the population sex ratio. Table 2 shows the parameters derived from the user supplied inputs, listed in computational order. To run the model, fishing mortality (F) was stepped from 0 to a specified upper limit while computing YPR and SPR for each value of F.

The model is capable of returning a suite of fishing mortality

TABLE 1.

Geoduck life history parameter estimates held constant for all study sites.

Parameter Description	Parameter Symbol	Value, Notes
Unfished ("virgin") spawning stock biomass (in kg); the spawning biomass when $F = 0$	$B0_s$	100,000 kg (only required to scale absolute biomass)
Instantaneous natural mortality rate (assumed constant for all ages)	M	0.0226
Weight-at-age (in g) based on length-at-age as derived from the von Bertalanffy growth function	w_a	$w_a = xL_a^y$ L_a = length (cm) at age a x = 0.349127 y = 2.972807
Maturity-at-age; the proportion of female geoducks of age a (in years) that are sexually mature	Φ_a	$\Phi_a = 1/(1 + \exp^{x a+y})$ x = −1.9 y = 9.5
Fishery selectivity-at-age; the proportion of geoducks of age a (in years) selected by the fishery	v_a	$v_a = 1/(1 + \exp^{x a+y})$ x = −1.5 y = 8.0
Beverton-Holt spawner-recruit shape parameter (Kimura 1988)	A	1
Proportion of males in population	p_m	0.5
Maximum (accumulator) age	a_{max}	25

benchmarks, such as F_{max}, $F_{0.1}$, and $F_{xx\%}$. For example, the fishing mortality rate that produces, over the long run, the maximum YPR corresponds to the F_{max} strategy, whereas $F_{0.1}$ represents a rate of harvest less than F_{max} (Deriso 1987, Gulland 1968).

The fraction of the unfished spawning weight per recruit remaining at a given level of fishing mortality was calculated as SPR/SPR0 and is achieved at a corresponding fishing mortality rate $F_{xx\%}$ where xx represents the ratio (SPR/SPR0)100. Model predictions of this fraction formed the basis for SPR-based fishing strategies. For example, the fishing mortality rate that resulted in a value of SPR/SPR0 = 0.35 corresponds to the $F_{35\%}$ strategy.

RESULTS

Natural Mortality

Sampled geoducks from 14 previously unfished sites ranged in age from 2 to 131 y (Fig. 2a). The mean age of geoducks was 46 y (standard error [SE] = 0.56, n = 2,157). The initial upper age limit for the catch curve was 110 y, because no 111-y-old geoducks were in our sample. Examination of residuals showed a single large negative residual at the 99-y age class (only one geoduck of this age was in our sample), and this age class was eliminated from the analysis as an outlier, based on the test given in Weisberg (1985). Both the Robson and Chapman (1961) Chi-square procedure and our *ad hoc* optimization procedure identified age 28 as the lower age limit for the catch curve. A Chi-square was used to test goodness of fit of fully selected ages (28–98) to a geometric distribution. The resulting Chi-square was highly significant (X^2 = 326.56, degrees of freedom = 68), indicating that the age frequency was not geometric in distribution and that data requirements for the Robson and Chapman model were not met. Ricker (1975) pointed out that in most stocks, difference in year-class strength is the major source of variability, in which case the best estimate of survival would be obtained from a catch curve analysis with equal weighting. The Ricker catch curve based on ages 28–98 (Fig. 2b) produced an estimate of M = 0.0226 y^{-1} (±0.0018 SE, n = 71, r^2 = 0.70).

Other Model Parameters

Goodwin (1976) calculated an allometric length-weight relationship for Washington geoducks in log-log form. We converted this to the more familiar power curve form $w_a = xL_a^y$, where w_a = weight (in g) at age a, L_a = shell length (in cm) at age a (Table 1). The proportion of males (p_m) in the geoduck population was set to p_m = 0.5 based on a 50:50 sex ratio for geoducks older than 10 y (Goodwin and Pease 1989).

The proportion of sexually mature geoducks at age (Φ) was estimated by fitting a simple logistic curve to maturity data from published sources. Anderson (1971) found that 50% of his sample of geoducks was mature at 75 mm and an age that he estimated to be 3 y. The Washington growth curves described above suggest that this length would be attained in roughly 5 y, depending on the site. Sloan and Robinson (1984) reported that geoducks mature at 5 y and reproduce for at least a 100-y period with no "reproductive senility." They stated that "unequivocally mature geoducks" were 6–103 y old (late-active males) and 12–95 y old (late-active females). On the basis of these two sources, we fit a logistic curve with the least-squares method and two data points, whereby 50% of the female geoducks would mature at 5 y and 100% by 12 y (Table 1).

The proportion of geoducks at age a selected by the fishery (v_a) was based loosely on Harbo et al. (1983), who reported that recruitment to the British Columbia geoduck fishery begins at 4 y and is complete by 12 y. To more conservatively model fishery selectivity, we fit a simple logistic curve using the least-squares method and two data points, whereby geoducks enter the fishery at roughly 4 y and are fully selected by 8 y (Table 1).

Nothing is known about the form or steepness of the S-R relationship for geoducks. We therefore set the Beverton-Holt shape parameter (A) equal to 1.0 for all model runs. In other words, we assumed that recruitment was independent of spawning stock abundance. This assumption is reviewed below in *Discussion*.

As a practical convenience, the equilibrium yield model uses an "accumulator age" category (a_{max}) as the final age category, encompassing all ages $a \geq a_{max}$. For this study, we set a_{max} = 25, which implicitly assumes that there are no significant changes in growth, selectivity, or maturity beyond age 24. This assumption is reasonable for geoducks, which reach asymptotic size between the ages of 10 and 20 y (Hoffmann et al. 2000).

Fishing Mortality Rates for Five Harvest Strategies

We ran the model for each site, varying only the growth parameters based on the analysis of growth presented in Hoffmann et al. (2000). The only sites where growth parameter estimates (specifically, the growth constant k) could be pooled were five of the six Hood Canal sites. In all other cases, site-specific growth parameters could not be pooled, and therefore separate model outputs

TABLE 2.

Description of derived parameters used in the geoduck equilibrium yield model.

Description	Derived Parameters	Notes
Number of geoducks surviving to the first age class (a = 1 year)	$N_a = p_m$ for males $N_a = 1 - p_m$ for females	p_m = proportion of males in the population (see Table 1)
Instantaneous rate of fishing mortality at age a	$F_a = Fv_a$	F = instantaneous rate of fishing mortality for fully selected age classes (v_a = 1); user-supplied. v_a = fishery selectivity at age a (see Table 1)
Instantaneous rate of total mortality at age a	$Z_a = M_a + F_a$	M_a = instantaneous natural mortality rate (see Table 1)
Annual rate of survival	$S_a = \exp(-Z_a)$	
Number of geoducks surviving to age a for $a > 1$	$N_a = N_{a-1}S_{a-1}$	
Average number of geoducks at age a	$\overline{N_a} = N_a(1 - S_a)/Z_a$ for $a < a_{max}$ $\overline{N_a} = N_a/Z_a$ for $a = a_{max}$	a_{max} = maximum (accumulator) age (see Table 1)
Average biomass (in kg) of geoducks at age a	$\overline{B_a} = \overline{N_a}w_a$	
Yield per recruit (in kg) at age a	$YPR_a = v_aF\overline{B_a} = F_a\overline{B_a}$	
Total yield per recruit (in kg) for all ages	$YPR = \sum_a v_aF\overline{B_a} = F\sum_a v_a\overline{B_a}$	
Spawning weight per recruit (in kg)	$SPR_a = \overline{B_a}\Phi_a$ for age a $SPR = \sum_a \overline{B_a}\Phi_a$ for all ages	Φ_a = proportion of mature females at age a (see Table 1)
Fraction of unfished spawning stock biomass remaining at a given level of fishing mortality	$P = 1 - (1/A)(1 - SPR/SPR0)$	A = Beverton-Holt shape parameter (see Table 1). SPR0 = unfished spawning weight per recruit (total SPR when F = 0)
Spawning biomass (in kg) when $F > 0$	$B_s = P\,B0_s$	$B0_s$ = unfished spawning stock biomass (see Table 1)
Recruitment (in numbers)	$R = (B_s/SPR0)/[1 - A(1 - P)]$	Reference: Kimura (1988)
Yield (in kg)	$Y = YPR(R)$	
Harvest rate for fully selected age classes (v_a = 1)	$\mu = F/Z[1 - \exp(-Z)]$	Reference: Ricker (1975)

were calculated for each site. All inputs except growth parameters were identical for each model run (Table 1). Growth parameters used as site-specific input are shown in Table 3.

Values of the instantaneous fishing mortality rate (F) for five commonly used constant harvest rate strategies are shown in Table 3. F_{max} is the fishing mortality rate that produces, over the long run, the maximum YPR. $F_{0.1}$ is a common alternative to F_{max} and is the rate of fishing mortality at which the marginal YPR is 10% of the marginal YPR for a lightly exploited fishery (Deriso 1987). $F_{35\%}$, $F_{40\%}$, and $F_{50\%}$ are SPR-based harvest rates that reduce SPR to either 35%, 40%, or 50% of the unfished level (Clark 1991).

F_{max} ranged from 0.053 to 0.100 depending on the site (Table 3). These rates correspond to annual harvest rates (μ) of 5.1–9.4% of the exploitable geoduck biomass. The Strait of Juan de Fuca region, represented by the single sampling site at Dallas Bank, produced the lowest value, whereas Fishermans Point in Hood Canal produced the highest value. The F_{max} strategy reduced SPR to 15–21% of the unfished level, depending on the site. Values for $F_{0.1}$ ranged from 0.028 to 0.037, corresponding to annual harvest rates of 2.7–3.6%. This strategy reduced SPR to 35–37% of the unfished level, depending on the site.

Values for $F_{35\%}$ were, predictably, nearly identical to the $F_{0.1}$ rates, ranging from 0.30 to 0.36 (μ = 2.9–3.5%). F values for the $F_{40\%}$ strategy ranged from 0.025–0.030 (μ = 2.4–2.8%), whereas those for the $F_{50\%}$ strategy ranged from 0.018–0.020 (μ = 1.8–2.0%).

Model Sensitivity to Parameter Estimates

All of the parameter estimates used to drive the model are subject to varying degrees of uncertainty. It is therefore reasonable to ask what might happen to our predictions if the true values of M or k, for example, were much lower or higher than our estimates. We tested the sensitivity of the model by running it with a range of values for each parameter in turn while holding all other parameters constant. Values ranging from one-tenth the "best" parameter estimate (from Tables 1 and 2) to three times the estimated value were used in the analysis. Only the fishing mortality rates corresponding to the $F_{40\%}$ strategy were calculated, but the trend for other strategies would be similar.

The model was most sensitive to the estimate of M, with $F_{40\%}$ values ranging from 0.003 to 0.068 as M was increased from one-tenth to three times our "best" estimate of M = 0.0226 (Fig. 3). The model was far less sensitive to the other parameter estimates, as evidenced by the relatively flat $F_{40\%}$ trajectories for values of the growth coefficient k, the selectivity constant γ, and the maturity constant γ. For example, varying the value of k from one-tenth to three times our best estimate resulted in $F_{40\%}$ values that ranged only from 0.021 to 0.033.

Use of Model Results to Set Annual Fishing Quotas

The model results presented above, together with an estimate of exploitable biomass, may be used to set annual fishing quotas. The first step in such a process is for managers to recommend one of the five harvest strategies described above, or an alternate strategy; the model is capable of returning F-values for any desired level of equilibrium spawning biomass or yield. The decision process involved in recommending a particular harvest strategy is by no means clear-cut, but some guidelines on risk-averse strategies from the recent fisheries literature are reviewed below in *Discussion*.

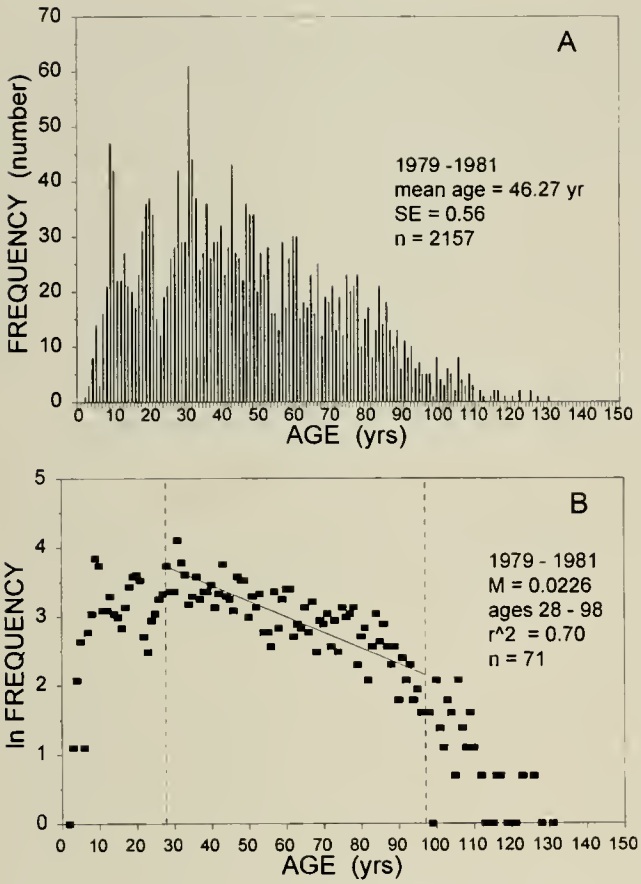

Figure 2. (A) Age frequency of geoducks sampled at 14 sites in Washington. (B) Catch curve used to estimate the instantaneous natural mortality rate (M) of geoducks.

Once managers reach a decision on the "best" harvest strategy, the corresponding F-value may be taken directly from the mean values in Table 3. This mean F-value is then converted to the harvest rate (μ) for fully selected age classes (Ricker's equation from Table 2). To produce the recommended annual fishing quota, the harvest rate is then simply multiplied by the estimate of harvestable biomass. For example, Washington managers have recommended and adopted an $F_{40\%}$ strategy for geoducks in all six management regions. This strategy is achieved with an instantaneous fishing mortality rate of $F = 0.028$ (mean value for all sites, Table 3); the corresponding annual harvest rate for fully selected age classes (μ) is 0.027, or 2.7% of the exploitable biomass. Annual dive survey data provide an estimate of exploitable biomass for each of six management regions. As an example, exploitable geoduck biomass in the Hood Canal Region in 1999 was estimated to be 18,185 t (Sizemore and Ulrich 1999), and the resulting annual quota was (0.027)(18,185 t) = 491 t.

DISCUSSION

Our primary objective in equilibrium modeling was to simulate the long-term results of various geoduck fishing strategies, both in terms of yield and SPR. Before discussing our results, it is perhaps necessary to explain why we attach such importance to geoduck harvest rate strategies, particularly since the differences between many of the modeled options may appear trivial.

In many fisheries, especially those in which biomass is small or estimated with great uncertainty, debating a 1% difference between annual harvest rate options would indeed be trivial. But in Washington's geoduck fishery, where the exploitable biomass is large (73,843 t in 1999; Sizemore and Ulrich 1999) and the price is high, even tiny incremental differences in the recommended harvest rate have tremendous economic significance. Moreover, because geoducks have a low M (and presumably a low intrinsic rate of increase), small differences in annual harvest rates can have profound cumulative effects on stock size, especially if the harvest rate is set too high. This is not to discount the importance of good biomass estimates, but we believe there are several reasons why Washington managers should place the greatest emphasis on improved harvest rate strategies rather than improved biomass estimates. First, biomass estimates for individual geoduck beds in Washington have coefficients of variation (CVs) averaging about 11%. Simulation tests suggest that biomass estimation errors of this magnitude are unlikely to result in substantial degradation of long-term harvest performance (Frederick and Peterman 1995). Second, even greatly increased sampling is not likely to improve biomass estimate CVs very much. Third and most importantly, errors in biomass estimation are assumed to be reasonably unbiased. An error in setting the annual harvest rate, on the other hand, will have a persistent and cumulative effect on stocks in only one direction, either underharvest or overharvest. We therefore believe that, given reasonable estimates of stock size, choosing a harvest strategy remains the most critical aspect of geoduck management.

In this study, we evaluated five common harvest strategies. Our model predicts that fishing at F_{max} will eventually reduce SPR to less than 20% of the unfished level, a threshold below which many fish stocks are assumed to collapse (Thompson 1993). Therefore, F_{max} should be considered a high-risk strategy for geoducks.

Less risky are the SPR-based strategies, three of which were evaluated here. In this study, we assumed that recruitment was independent of stock size at all levels of fishing (Beverton-Holt parameter $A = 1.0$). Although this is the common default assumption in cases in which the S-R relationship is unknown, the risk inherent in this assumption is that given an existing but undetected S/R relationship, $F_{x\%}$ can be greater than F_{MSY} (the preferred fishing rate with a known S/R function; MSY, maximum sustainable yield). As an alternative to F_{max}, SPR-based strategies seek to preserve some minimum level of spawning biomass and at the same time produce yields that are close to the MSY. In an attempt to find fishing strategies that are robust for any likely S-R relationship, recent modeling studies have simulated groundfish yields using a range of typical life history parameters and realistic S-R models. Clark (1991) showed that fishing at $F_{35\%}$ would achieve at least 75% of MSY for a wide range of deterministic S-R relationships. On the basis of his results, $F_{35\%}$ has been adopted as a target rate for a number of fish stocks in Alaska and the U.S. Pacific coast. Clark (1993) later revised his recommendation to $F_{40\%}$ after considering variability in recruitment, but remarked that "it would be silly to argue very hard for or against any specific rate between $F_{35\%}$ and $F_{45\%}$." Mace (1994) also recommended $F_{40\%}$, which she claimed was a modest improvement over $F_{35\%}$. She states that $F_{40\%}$ represents a risk-averse fishing strategy in the common situation in which there is adequate information to place bounds on all relevant life history parameters except the S-R relationship. Quinn and Szarzi (1993) modeled clam fisheries in Alaska and recommended SPR-based strategies equivalent to a range of $F_{30\%}$–$F_{45\%}$.

As noted earlier, Washington managers have adopted an $F_{40\%}$ strategy for geoducks, which corresponds to $F = 0.028$ (averaged

TABLE 3.

Benchmark instantaneous fishing mortality rates for fully selected geoducks (v_a = 1.0) from seven sites in Washington.

Region	Site	n (sites)	L_∞ (cm)	k	t_0	F_{max}	$F_{0.1}$	$F_{35\%}$	$F_{40\%}$	$F_{50\%}$
South Sound	Hunter Point	1	16.4	0.23	0.72	0.090	0.036	0.036	0.029	0.020

Mean of all sites						0.075	0.033	0.033	0.028	0.019

Model inputs except growth parameters are from Table 1. Growth parameter estimates are from Hoffmann et al. (2000).

over all sites) and annual harvest rate (μ) of 2.7% of current exploitable biomass. British Columbia managers calculate annual quotas using a fixed harvest rate of 1% (Campbell et al. 1998), but this rate is applied to the estimated *virgin* biomass rather than current biomass estimates, as is done in Washington.

A secondary objective of our study was to determine which of the estimated geoduck life history parameters were most influential in predictions of yield and SPR. The model was most sensitive to the estimate of natural mortality (M), whereas growth, selectivity, and maturity parameters had relatively little effect on SPR-based fishing mortality rates. This suggests that future research monies are best spent making more reliable estimates of M.

Because our model is an equilibrium model and admittedly sensitive to the estimate of M, one could ask how it might cope with time varying natural mortality. If it were possible to construct a functional relationship between specific, measurable categorical variables—such as predator density, or sea temperature and natural mortality rates—and if these categorical variables were themselves predictable, one could estimate the expected changes in M. With a credible estimator, the equilibrium model could be converted to a dynamic pool model and revised estimates of F could be derived for a specific future time interval of interest. Such an application would be highly dependent on the accuracy and precision of the predictive functions, not only the functions related to M but also the expected annual recruitment. We are doubtful that this approach would become profitable. Alternatively, annual or fixed interval updates of the equilibrium F could be computed using revised estimates of M.

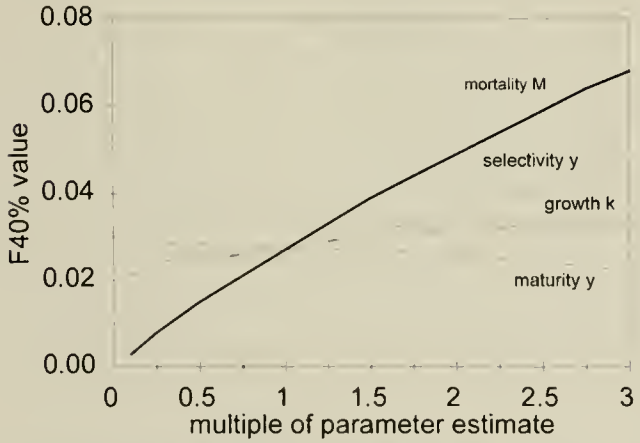

Figure 3. The effect of different parameter estimates on model-derived $F_{40\%}$ values. Numbers on the X-axis represent multiples of the "best" parameter estimates from Table 1 (mortality, selectivity, and maturity) and Table 3 (growth parameter k).

If natural mortality varies over time, the true $F_{40\%}$ would rise and fall proportionately with the change in M (Fig. 3). We would err in the application of our equilibrium F dependent on the trend in M. If M fluctuates around some normally distributed mean, then on average our equilibrium F is probably reasonable. If there is a significant periodicity in the trend in M (a long duration decline, for example) and it goes unrecognized, application of the equilibrium F risks overharvest of the resource. Managers could impose a safety valve by creating a harvest policy that reduces the exploitation rate below that derived from the preferred F (e.g., 0.75 F), but it would be speculative whether this precaution was sufficient to account for real variability in M. Models of stochastic variability in recruitment have led scientists to suggest maintaining a larger spawning biomass and therefore adoption of a lower preferred F (e.g., $F_{40\%}$ rather than $F_{35\%}$) (Mace 1994, Clark 1993).

Our estimate of M = 0.0226 is similar to estimates from British Columbia. Sloan and Robinson (1984) estimated M = 0.035 at a single site, while Breen and Shields (1983) reported M = 0.01–0.04 in five populations. Noakes (1992) estimated M = 0.03–0.04 at three sites. Both our estimate and the British Columbia estimates relied on the catch curve method, which assumes that mortality rate is uniform with age and that recruitment has been constant over the range of age groups analyzed. There is some suggestion in our age-frequency data that a shift in geoduck recruitment has occurred that could have biased the estimate of M. Age frequencies did not begin to decline until about age 25, a pattern in catch curves that is often due to inefficient sampling of younger age classes. But for geoducks, which grow quickly and are fully selected by the commercial fishery at half this age (Harbo et al. 1983), sampling inefficiency is not a plausible explanation for the low numbers of geoducks in the 10–25-y age group. Instead, low numbers of 10–25-y-old geoducks may indicate poor recruitment during the 15-y period before sampling. This suggests that recruitment declined during the period 1955–1970 (before the advent of a fishery) and perhaps more recently. Sloan and Robinson (1984) suggested the possibility of a similar decline in recruitment during the same time period in British Columbia.

Thus, catch curve estimates of M for geoducks based on older age classes may not accurately represent current trends in natural mortality. They likewise reveal nothing about M for younger geoducks. In either case, our results indicate that biases in the estimate

of M will have a major influence on model-based predictions of yield and SPR. Independent estimates of M should therefore be a high priority for research. Given the fact that geoducks are entirely sedentary, direct or "known fate" estimates of M may be possible if a reliable and noninvasive tag can be developed. Such straightforward measurements of annual mortality would rely on fewer assumptions than the catch curve method and might also provide age-specific and area-specific estimates M.

A final caveat related to the use of simple yield models such as ours is that they do not take into account the spatial distribution of harvested animals. Spatial structure is frequently ignored in the management of finfish stocks, because it is assumed that survivors are being continually mixed by movement. Under this "dynamic pool" assumption, it does not matter whether the annual quota is taken in small amounts over the entire fishing area or taken entirely within a tiny corner of that area. But as Orensanz and Jamieson (1998) point out, the dynamic pool assumption may be risky when applied to sedentary benthic species such as geoducks. More research should therefore be devoted to the long-term effects of various spatial harvesting strategies on yield and spawning biomass of geoducks. An experiment of this sort is underway in Washington, where geoduck densities at 15 commercial beds are being monitored before and after fishing to estimate an empirical rate of population recovery. If it is based on a long span of time, an empirically determined turnover (i.e., recruitment) rate for commercially fished geoduck beds could be used to validate, improve, or replace the harvest rate strategies on the basis of structural models.

ACKNOWLEDGMENTS

We thank Tom Jagielo and Dr. Annette Hoffmann for statistical advice and reviews of an earlier draft. Lynn Goodwin, Warren Shaul, and Conrad Budd collected and read the age samples. Don Rothaus and Bob Sizemore provided extensive reviews of earlier drafts. Michael Ulrich drew the site map. Don Flora, Dr. Bob Conrad (Northwest Indian Fisheries Commission), and Dr. J. M. ("Lobo") Orensanz (University of Washington) reviewed earlier drafts and made helpful suggestions. We thank Dr. W. G. Clark for providing the original FORTRAN-coded equilibrium yield model. Finally, we thank the anonymous reviewers who made suggestions on the final draft.

ABSTRACT Spores of a microsporidian parasite were found in the queen scallop, *Aequipecten opercularis* (L.), collected from several coastal sites around the United Kingdom. Developing spore stages were detected in contact with the host cell cytoplasm. Infected host cells formed aggregates in the connective tissue of the digestive gland. Fully mature spores were found free within blood vessels. These spores exhibited a dome-shaped polaroplast, a diplokaryon, a posterior vacuole, and an isofilar polar tube, with seven to eight coils in a single row. In immature spores, the number of coils in the polar tube varied, with some having 7 to 8 coils and others having 10 to 12 coils.

KEY WORDS: Microsporidian, spores, scallop, *Aequipecten opercularis*, parasite

INTRODUCTION

Scallop species are of commercial interest in many parts of the world. In Europe, the main species exploited is the great scallop (*Pecten maximus*), which is the subject of important fisheries in France, Ireland, the United Kingdom, and Norway, where it is cultivated on a small scale. There is also a significant natural fishery for the queen scallop, *Aequipecten opercularis*. This species is distributed from northern Norway and the Faroe Islands to the Mediterranean and Adriatic Seas. It lives in depths ranging between 18 and 46 m on fine sand, fine gravel, or sandy gravel. The main areas of fisheries for this species lie along the western coasts of the British Isles and France but also include the Shetland Isles and Moray Firth in the northeast and both sides of the English Channel (Ansell et al. 1991, Brand 1991).

Since little is known on the natural disease status in these two species, a survey was undertaken to collect baseline data on parasites and possible pathogens in natural, apparently healthy populations. During this study, a microsporidian was found in the digestive gland of the queen scallop, and electron microscopy (EM) studies were undertaken for characterization and identification of this parasite.

Microsporidians are eukaryotic, obligate intracellular parasites of almost all animal phyla. The most common hosts are arthropods and fish (Canning 1990). Only a few microsporidians have been reported from bivalves. Comps et al. (1975) found an unidentified species in *Cardium edule* and Jones (1981) described *Microsporidium rapua* from the oyster *Ostrea lutaria* in New Zealand. In mytilids, a microsporidian parasitizing the oocytes has been described by Figueras et al. (1991a, 1991b) who found *Steinhausia mytilovum* in *Mytilus galloprovincialis* from Spain and in *Mytilus edulis* from the United States. Villalba et al. (1997) observed the same parasite in ova of *Mytilus galloprovincialis*, and Sagristá et al. (1998) described the developmental cycle and ultrastructure of this protistan in *M. galloprovincialis*.

In this study, the spores of a microsporidian parasite from the queen scallop are described.

MATERIALS AND METHODS

A total of 454 adult queen scallops (*A. opercularis*) were sampled during the period July 1997 to April 1998. The sampling localities are shown in Figure 1. The localities and dates of sampling are shown in Table 1.

For histology, transverse tissue sections were taken that included the digestive gland, kidney, gills, gonad and mantle, and they were fixed in Davidson's fixative (Shaw and Battle 1957) for 24 h. The tissues then were dehydrated, cleared, infiltrated with paraffin wax, and sectioned at 5–6 μm. The routine stain used for all samples was Gill's hematoxylin and aqueous eosin. Selected samples were stained with special stains: Farley-Feulgen (Farley 1969) for identifying DNA, and Giemsa for staining presumptive parasites. For each sample, one section was cut, and the slides were examined using a Reichert Polyvar microscope. Photographs were taken with a photomicroscope (E800 Eclipse, Nikon, Tokyo, Japan).

For transmission EM, 1-mm^3 pieces of digestive gland from each specimen sampled for histology were fixed in 3% glutaraldehyde in 0.2M cacodylate buffer with 1.75% NaCl, for 2 h at room temperature, and were washed in the same buffer. After histological assessment, those samples found to harbor the microsporidian were further processed for EM. Tissues were washed another three times in 0.2M cacodylate buffer with 1.75% NaCl, and were postfixed for 1 h in 1% osmium tetroxide in the same buffer. After washing twice with buffer, they were rinsed in distilled water, stained for 1 h *en bloc* with 2% aqueous uranyl acetate, dehydrated in ethanol, washed in propylene oxide, and embedded in Epon 812 (premix, BDH). Semithin sections, 1 μm thick, were cut on a Reichert Ultracut S microtome and were stained with toluidine blue. Ultrathin sections were cut with a diamond knife and were stained with aqueous uranyl acetate and lead citrate. The sections were viewed and photographed with an electron microscope (EM 900, Zeiss) at 50 kV.

Measurements from stained histological or semithin sections were made using a Nikon E800 microscope with LUCIA screen

Figure 1. Map of England and Wales showing the sampling sites.

measurement system. The number of longitudinally sectioned spores that were measured is indicated in each case.

RESULTS

The prevalence of microsporidiosis in *A. opercularis* is given in Table 2.

Spores were found in two different locations in the digestive gland of *A. opercularis*. Immature spores were found in the cytoplasm of connective tissue cells, and mature spores were observed free in blood vessels. In some scallops, both kinds of spores were seen together in the same section; in others, only one kind of spore was found (Fig. 2).

The cells with maturing spores formed aggregates measuring approximately 300 μm in diameter. They were found in two of the 80 resin blocks examined. The whole aggregate (Fig. 2) as well as each infected host cell was surrounded by layers of fibroblast-like cells, as shown at the EM level (Fig. 3). In infected cells, the nucleus could be observed in some sections. The cytoplasm generally was degraded, although mitochondria could still be recognized. The presence of a sporophorous vesicle was not confirmed, the spores being in direct contact with the host cytoplasm. The spores measured 2.3 (range 1.8–2.8) × 1.3 (range 1.1–1.9) μm (n = 20), had an elongate-ovoid shape, and showed different degrees

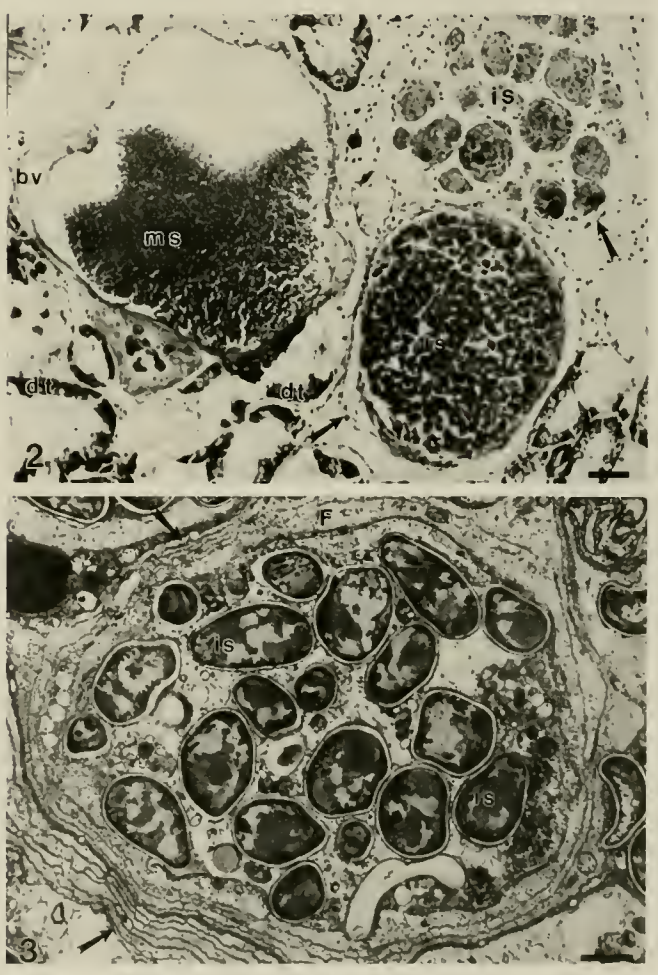

Figure 2. Histological section showing mature spores (ms), free in a blood vessel (bv), and two aggregates of host cells containing immature spores (is). The upper aggregate is less mature, and both aggregates are surrounded by fibroblast-like cells of host origin (arrows); dt = digestive gland tubule (Giemsa stain; bar = 50 μm).

Figure 3. Transmission electron micrograph of one infected cell with immature spores (is), surrounded by fibroblast-like cells of host origin (F). The cell membranes of these cells form layers around each infected cell (arrows) (bar = 1 μm).

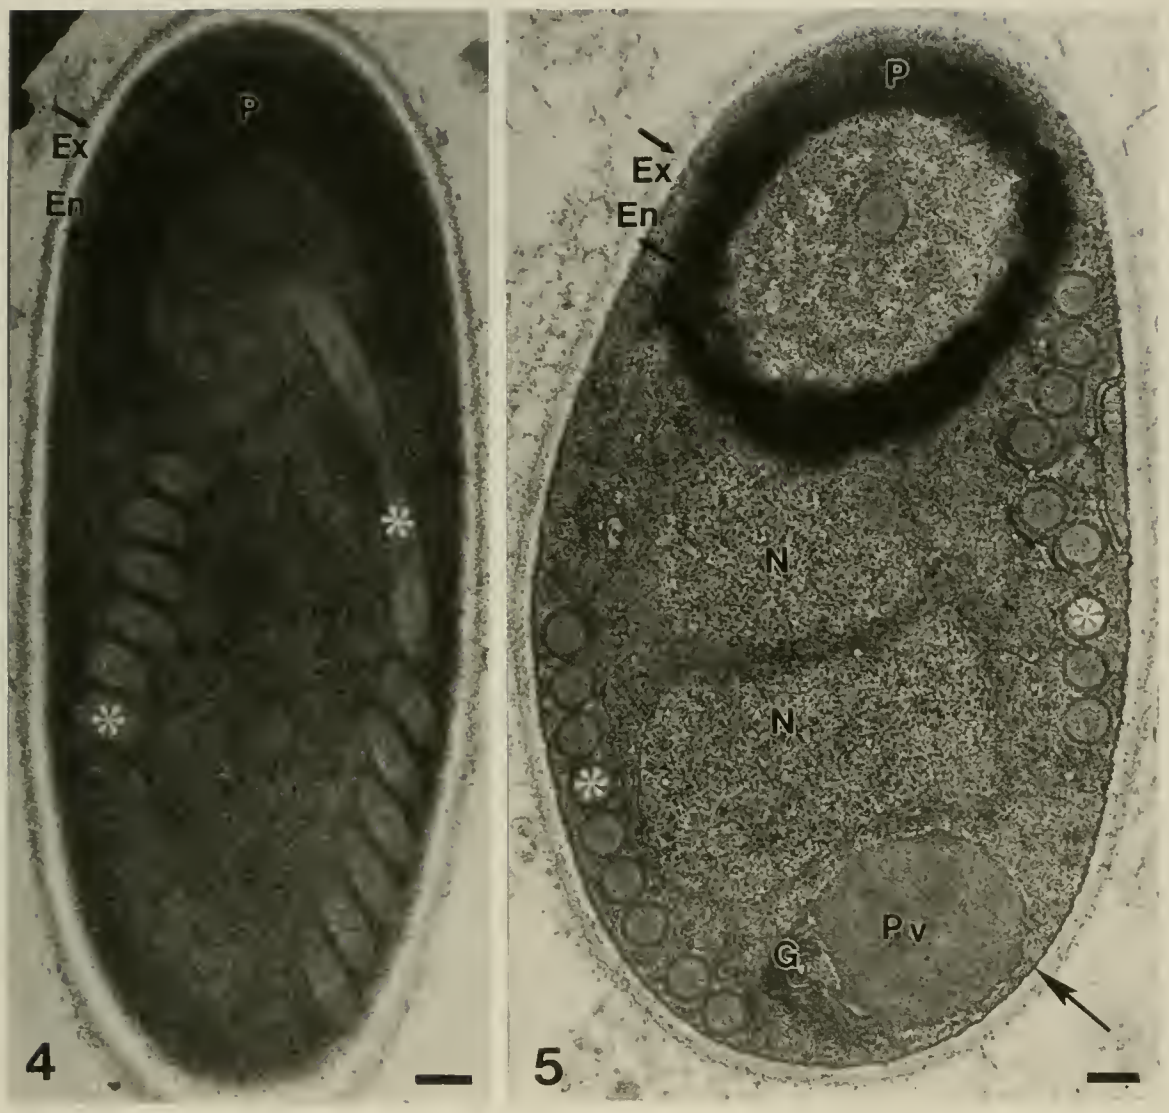

Figure 4. Mature spore viewed in longitudinal section. The exospore (Ex) and the endospore (En) can be observed. Internally, the polaroplast (P) and oblique sections of the polar tube can be seen (*) (bar = 0.1 μm).

Figure 5. Electron micrograph of a slightly oblique section of a mature spore. The outer covering consists of an exospore (Ex), endospore (En), and the cell membrane (arrow). The polaroplast can be observed at the anterior end of the spore, with the two nuclei (N) forming a diplokaryon in the central region of the spore. The coils of the polar tube in transverse section (*), the posterior vacuole (Pv), and in close proximity Golgi-like membranes (G) can also be seen (bar = 0.1 μm).

of maturation. It was not possible to determine whether the immature spore contained a single nucleus or a diplokaryon, since areas considered to be nuclear did not appear to be delimited by an envelope. The polar tube was isofilar, with 10 to 12 coils in a single row. Some spores showed a shorter polar tube, with seven to eight coils. The spores were limited by an inner electron-lucent endospore and an outer electron-dense exospore.

Mature spores were found in only one of the resin blocks examined. They were located in blood vessels and were elongate-ovoid in shape, measuring 2.3 (range 1.9–3.2) × 1.2 (range 0.8–1.7) μm (n = 9). They were limited by an outer exospore and an electron-lucent endospore covering the plasma membrane (Figs. 4, 5). The polar tube was inserted into the anterior anchoring disc (Fig. 6), passing through the center of the spore, and then, in the posterior two thirds of the spore, were wound in most cases into 7 to 8 coils (Fig. 7), and exceptionally into 9 coils (Fig. 5), and were aligned in a single row. The polar tube was isofilar, measuring 83.5 nm in diameter. A conspicuous, dome-shaped polaroplast occupied the anterior third of the spore, enclosing the straight region of the polar tube and terminating close to the coiled polar tube (Fig. 4). Two spherical nuclei were closely apposed, forming a diplokaryon. Each measured up to 0.88 μm in its longest axis and was flattened in the zone of contact with the other nucleus (Fig. 7). The diplokaryon was located in the central third of the spore, between the polaroplast and the posterior vacuole. The latter was limited by a single membrane, with Golgi-like membranes often present in close association (Fig. 5).

DISCUSSION

This is the first time that a microsporidian infection has been reported in any scallop species.

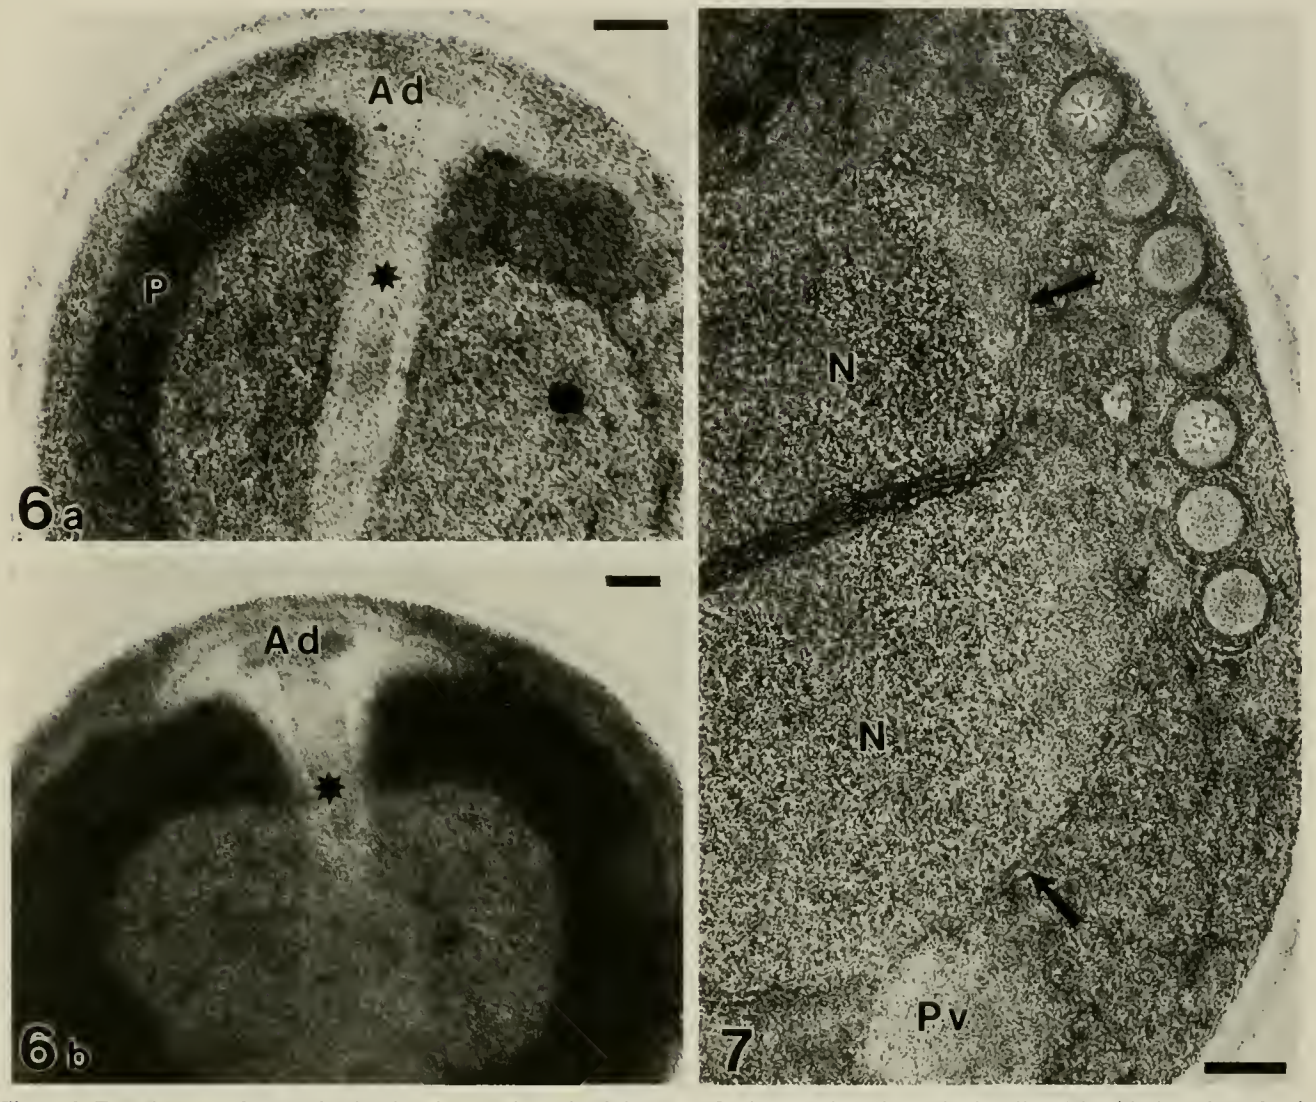

Figure 6. Two electron micrographs showing the anterior pole of the spore. In these sections the anchoring disc (Ad) with the polar tube (*) attached can he seen. The polaroplast (P) is also apparent (bar = 50 nm).

Figure 7. Electron micrograph from a spore sectioned through the nuclei (N) of the diplokaryon. The nuclear envelope can he clearly observed (arrows). The polar tube (*) has seven coils, and the posterior vacuole (Pv) is also present in this section (bar = 0.5 μm).

Spores were found in two different locations in the digestive gland. Immature spores were located intracellularly, and mature spores were located within blood vessels.

We were unable to find any of the earlier stages of this parasite in the scallops examined. Unlike in other microsporidian species, where developmental stages and spores are present concurrently (Comps et al. 1979, Amigó et al. 1996, Johnson et al. 1997, Larsson et al. 1997), in this species only one developmental stage, the spore, could be observed. It is possible that the early stages were present in a tissue other than that of the digestive gland. Since the cells infected by the microsporidian appear to be hemocytes, the potential for infection in tissues apart from the digestive gland, such as the intestine, stomach, and gills should be recognized. Additional EM studies are needed to investigate this possibility. That the microsporidian has an intermediate host within which the early developmental stages could be present should also be considered. Although most microsporidians have only one host, there are several examples of the requirement for an intermediate host (i.e., *Amblyospora*) (Andreadis 1985, Becnel 1992).

The immature spores differed slightly in the length of the polar tube, some having 7 to 8 coils, and others showing 10 to 12. The presence of two types of spores differing mainly in the length of the polar tube has been described for other microsporidian species, i.e., *Nosema* spp. (Iwano and Ishihara 1991) and *Nosema muscidifuracis* (Becnel and Geden 1994). These authors suggest that a shorter polar tube is characteristic of spores involved in infection of other cells in the same host, the longer polar tube belonging to spores that are involved in transmission from host to host. All the mature spores examined in the present study had a short polar tube, but they were all from one specimen and from the same resin block. We presume that mature spores with a long polar tube also exist, because we found them in the immature spores. Despite the large number of resin blocks examined, we did not succeed in finding the mature spores with 10 to 12 coils of the polar tube.

Fully mature spores showed clear evidence of a diplokaryon. This feature, together with a polar tube consisting of eight coils in a single row, the overall dimensions, and the fact that it is infecting an invertebrate host, places this microsporidian near to the genus

Pseudopleistophora (Sprague et al. 1992), a microsporidian first described as *Pleistophora* sp. parasitizing eggs of the annelid *Armandia brevis* by Szollosi (1971).

One important point that needs to be explained is the mechanism by which immature spores contained in individual cells later appear as free, mature spores in blood vessels. No transitional forms were seen in the current study, but in some reports, as the maturation of the spores progresses, the host cells start to loose their plasma membranes and become a syncytium (Weiser 1976). In this way, the spores would be released to reinfect adjacent cells or to become phagocytosed and perhaps migrate to other tissues.

No host reaction against this microsporidian was seen, other than a thin capsule made by fibroblast-like cells. This protistan does not seem to be a threat to queen scallops, as those sampled showed no evidence of poor condition. However, if these scallops become stressed due to changes in temperature, salinity, or crowding, as occurs in culture situations, the parasite could potentially become harmful to the host (Sindermann 1990). Despite the high prevalence of microsporidiosis in animals from a variety of locations around the United Kingdom, the impact of this parasite on wild populations of *A. opercularis* remains unknown. Further studies are needed to investigate the pathogenicity of the microsporidian in *A. opercularis* held in laboratory conditions under different temperatures and stocking densities. In addition, the identification of potential intermediate hosts and early developmental stages of the parasite are required for a specific identification of this microsporidian.

ACKNOWLEDGMENTS

K.B.L. thanks The British Council for a fellowship that allowed her to work for one year in the United Kingdom, and also MAFF funding, which contributed to this work. The authors also want to thank Dr. Eduardo Couve for access to the electron microscope at the Universidad de Valparaíso, Valparaíso, Chile, and Mr. Fidel Vargas for his skillful technical assistance.

EVALUATION OF THREE METHODS OF BOTTOM CULTURE OF THE TROPICAL SCALLOP *EUVOLA (PECTEN) ZICZAC* (L. 1758)

LUIS FREITES V.,[1] ANÍBAL VÉLEZ AND CÉSAR LODEIROS

Universidad de Oriente
P.O. Box 245
Cumaná 6101
Venezuela

ABSTRACT Three methods were used to study the growth and survival of juvenile *Euvola ziczac* (initial shell height of 40.4 mm SD = 4.2), and initial dry mass tissues of 0.35 g (SD = 0.01), which were set out at a density of 15 individuals m^{-2} on a sandy bottom at Turpialito in the Golfo de Cariaco, Venezuela. The first method was applied on an area of 3 × 5 m (15 m^2) with minimum demarkation (0.20-m low walls) on the bottom, the second method was applied on 1 × 1 m corrals with 1-m high walls, and the third method on 1 × 1 × 1 m cages with bottom and top covers. Both treatments with high walls were conducted with 15 replicates. We could not quantify growth and survival in the first treatment, because the rate of escape was >80% $month^{-1}$ (12 scallop m^{-2} $month^{-1}$). In the corrals, the escape rate increased progressively from 4% (1 scallop m^{-2} $month^{-1}$) to 36% (5 scallop m^{-2} $month^{-1}$), suggesting that the swimming ability of *Euvola ziczac* increased with size from an initial 40.4 mm to final 69.7 mm in shell height obtained in this study. No scallops escaped from the cages, but survival was less than in the corrals. Our observations suggest that the most appropriate bottom culture method would be corrals with walls higher than 1 m.

KEY WORDS: *Euvola ziczac*, bottom culture, scallop, enclosure, grow-out

INTRODUCTION

Euvola ziczac is a functional hermaphrodite scallop present from Cape Hatteras, North Carolina, throughout the Gulf of Mexico and the Caribbean Sea to southern Brazil off Santa Catarina (Abbott 1974). Although *Euvola ziczac* does not form dense natural banks able to support commercial fisheries activity, the species is considered to have great potential for commercial aquaculture activity off the Bermudas, Columbia, Venezuela, and Brazil (Hernández 1990, Vélez and Lodeiros 1990, Waller 1991, Castellanos et al. 1997). In Venezuela, several studies have determined aspects of biological feasibility for culture in the marine environment under hanging culture conditions (Freites et al. 1993, Freites et al. 1995, Freites et al. 1996, Lodeiros and Himmelman 1994). In this manner, rapid growth (up to 30–35 mm) and high survival rate have been attained. However, in larger sizes, diverse factors intrinsic to suspended culture, such as fouling (Lodeiros and Himmelman 1996), wave action (Freites et al. 1999), and food quality (Hunaulth et al. unpublished data), linked with unfavorable periods of high temperature, low available food, and reproduction effort in this species, generating stressful conditions, which lead to a decrease in growth and survival, have been noted (Lodeiros and Himmelman 1994, Lodeiros and Himmelman 2000). However, when *Euvola ziczac* is cultured in contact with the sandy substratum on the seabed (its natural habitat), high growth and survival rates have been noted, considering bottom culture as the most appropriate for the grow-out stage of the species (Vélez et al. 1995, Hunaulth et al. unpublished data).

Studies of the feasibility of various bottom culture techniques have been made for numerous pectinid species including *Chlamys farreri* (Wang et al. 1992), *Placopecten magellanicus* (Kleiman et al. 1996), *Pecten maximus* (Cliche et al. 1994, Dao et al. 1995), *Patynopecten yessoensis* (Aoyama 1989, Ito 1991), *Argopecten circularis* (Caceres-Martínez et al. 1986; Maeda-Martínez et al. in press), and *Pecten novaezelandiae* (Bull 1991). So, bottom culture is an alternative that has shown important levels of profitability in other scallop species. This is because of a lower investment in equipment, consumables, and maintenance than with the hanging method (Frishmand et al. 1980, Felix-Pico et al. 1991, Gilbert and Leblanc 1991, Wang et al. 1992, Kleinman et al. 1996).

In this manner, the aim of this study was to evaluate the growth and survival of scallop *Euvola ziczac* applying two bottom culture grow-out methods: with barriers in the cage and corral enclosures and with no barriers, to obtain market size.

MATERIALS AND METHODS

This study was conducted over a 6 month period (February 27–September 7, 1994) off the south coast of the Golfo de Cariaco, eastern area of Venezuela (Fig. 1). The individuals used in the experiment were obtained from a hatchery under controlled conditions at the end of August 1993, following the methodology described by Vélez and Freites (1993). Scallops were held in suspension for intermediate culture following the methodology described by Freites et al. (1993, Freites et al. 1995) until the initial mean shell height for the study of 40.4 mm (SD = 4.20) and initial dry mass tissues of 0.35 g (SD = 0.01) was obtained. A total of 720 individuals of *Euvola ziczac* were divided into three batches of 240 individuals each and thereafter, we took 15 individuals for each batch to the initial sample. Later, the remaining 225 individuals of each batch were allotted to the cages, corrals, and the barrier-free method. In the case of the enclosures, 15 replicates were introduced, 12 of which were experimental and three replacements. The latter were introduced to maintain density of the individuals reduced by the effects of mortality and escape. In the case of the barrier-free method, a total area of 15 m^2 was evaluated.

The cages measured 1 × 1 × 1 m, built with galvanized iron bars 8 mm in diameter, lined on the six sides by a galvanized wire mesh

[1]Address correspondence to: E-mail: lfreites@cumana.sucre.udo.edu.ve or lfreites@iim.csic.es

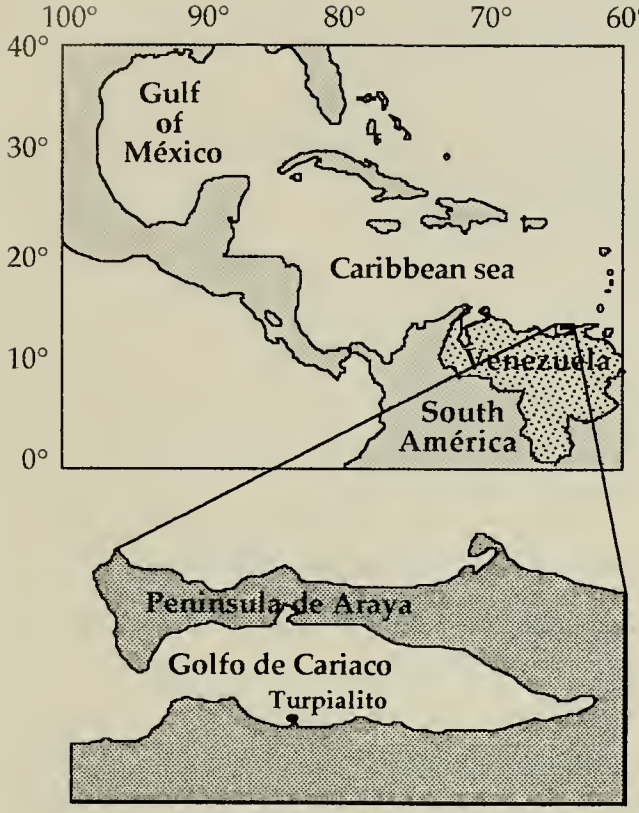

Figure 1. Geographical location of the study area.

with a 30-mm diameter opening (Fig. 2a). The corrals were built of the same size and with the same materials as the cages, except that the galvanized mesh was not fitted on the top and bottom parts (Fig. 2b). Both types of enclosures were buried 7–8 cm into the sand to allow the scallops in cages also to bury, and in case of the corrals, to avoid the escape of individuals under the enclosure and at the same time, to avoid entry of such predators as gastropods and crabs. The individuals in the barrier-free method were distributed in the area marked out beforehand by galvanized mesh, but with an edge of 20 cm. This was used to mark out the original area and thus enabling control of the density but not to act as a barrier (Fig. 2c). Both cage and corral methods were randomly placed at a depth of 7–8 m by a SCUBA diver. Density was a common parameter (15 individuals m^{-2}) both for the enclosures and for the barrier-free method.

Growth of individuals in the enclosures was followed by sampling the three replicates of five individuals (15 individuals) taken randomly, by previously allotting them random numbers. These samples were obtained over approximately 60 days. Also, the number of dead and live individuals was quantified monthly in all the experimental replicates in terms of determining mortality, escape, and monitoring the density of individuals.

The parameters for evaluating growth were shell height (distance between the anterior–posterior margins taken with a Vernier calliper with 0.01 accuracy) and the dry mass of the shell, gonad, muscle, digestive gland, and remaining somatic tissues (dried at 80 °C for 72 h).

Because there was an initial escape rate on the order of 84% of the individuals placed in the original area with the barrier-free method and because these could not be recovered, the evaluation of this method could not continue. Moreover, because of scallop in corrals escaping, we could not continue the evaluation of methods for longer than the 6 months of the study. To evaluate the results on the enclosures, cages, and corrals during the experimental period, the paired student's t test was applied to all growth parameters. Also, in terms of evaluating the masses and heights attained at the end of the study, the nonpaired student's t test was applied. To evaluate the survival rate, because the data were incompatible with assumed normal levels, analysis was conducted by nonparametric tests not correlative to those previously noted (Wilcoxon and Mann-Whitney range tests, respectively, following the recomendations in Zar (1984). For all test a $\alpha = 0.05$ was applied.

RESULTS

Escape

At the start of the experiment, an 84% escape rate was found (12 scallops m^{-2} $month^{-1}$) from the original area using the barrier-free method (Table 1). Furthermore, despite having searched an approximate area of 2500 m^2 taking the original area as the center, none of the individuals (0% recovery) was recovered, so that we were unable to continue with the evaluation. In the corrals, a progressive increase in monthly escapes was noted, from 4% (1 scallop m^{-2} $month^{-1}$) rising to 36% (5 scallops m^{-2} $month^{-1}$), observed at the end of the experiment (Table 1). In this way, the ratio of growth in shell height with the percentage increase in escape of individuals reared in cage was directly proportional ($P < 0.05$, $r^2 = 0.89$; $b = 2.15$). No scallops escaped from the cages.

Survival Rate

Monthly survival rates in the two enclosures showed similar trends (Fig. 3a) (Wilcoxon test, $P = 0.679$). At the end of the study, however, accumulated mortalities result in a significantly lower survival rate of the individuals in cages (51%); whereas, in the corrals, it was in the order of 78% (Fig. 3b) (Mann-Whitney test, $P < 0.05$).

Shell Size and Mass

Growth curve trends in shell height, both for individuals in cages and in corrals, were similar throughout the study period (paired student's t-test, $P = 0.912$), with the exception of the last sampling, where a reduction in the growth rate of cage-reared individuals was observed (Fig. 4a). At the end of the experimental period, the individuals reared in corrals had an average of 73.1 ± 2.34 mm; whereas, the average for the cages was 69.7 ± 3.93 mm. These differences, however, were not significant (nonpaired student's t-test, $P = 0.082$). The dry mass of the shell showed a growth pattern similar to that of shell length during almost the entire study period (Fig. 4a, b), but in this case, significant differences were noted (paired student's t-test, $P < 0.05$). So, there were significant differences (nonpaired student's t-test, $P < 0.05$) noted in the shell growth rates at the end of the study between scallops in corral (26.5 ± 2.61 g) compared to the individuals maintained in cages (23.9 ± 3.72 g).

Somatic Tissue Mass

The growth trend for somatic tissues muscle, digestive gland, and the remaining somatic tissues observed during the study period in cages and corrals, (Fig. 4c, d, e), showed no significant differences (paired student's t-test, $P = 0.719$, 0.679, and 0.369, respectively), despite the fact that these showed divergences in the

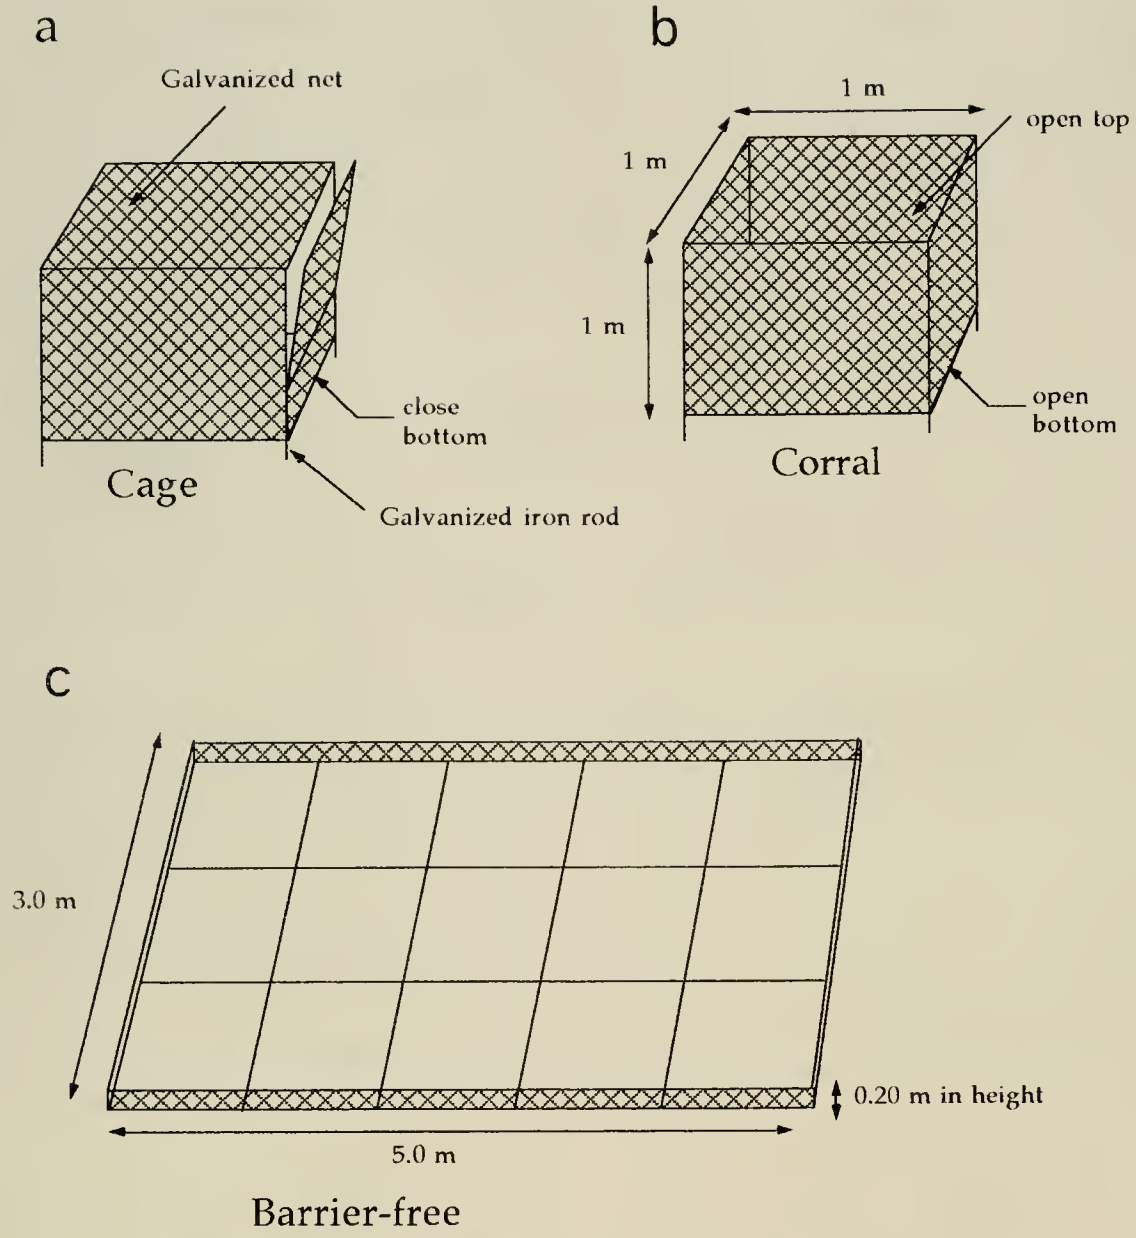

Figure 2. Design of enclosure cages (a) and corrals (b) and the barrier-free method (c).

latter period of the sampling, particularly in the remaining somatic tissues of both groups of individuals. Also, the decrease in growth of the mass of remaining tissues and gonads of individuals maintained in cages, observed at the end of the experimental period, contrasted with the increase in mass of these tissues in the corral-reared individuals (Fig. 4d, f), in such a manner that these were significantly greater at the end of the experimental period (nonpaired student's t-test, $P < 0.05$). In the case of the muscle mass in individuals reared in cages and corrals, no significant differences were shown at the end of the study period (nonpaired student's t-test, $P = 0.947$).

DISCUSSION

Our results showed that by applying the bottom culture method, in the course of approximately 1 year (from fertilization of the oocytes), sizes and biomasses considered as commercially feasible

TABLE 1.

Monthly escape (%) of the scallop *Euvola ziczac* observed during the study in the methods evaluated: barrier-free and cage.

Month	Methods	Shell Height	% Escape
April	Barrier-free*		84
	Corrals	54 mm	4
May	Corrals	59 mm	10
June	Corrals	65 mm	18
July	Corrals	67 mm	33
September	Corrals	70 mm	36

In the cages, the percentage of escape was always of 0%.
* We were unable to continue with the evaluation.

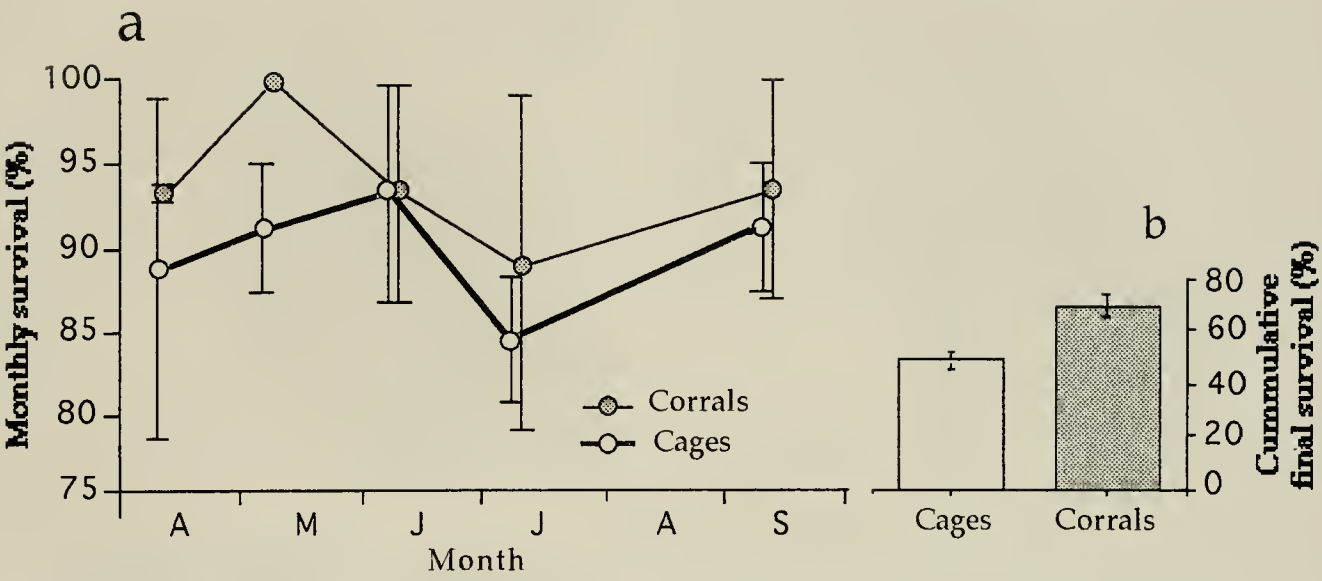

Figure 3. Monthly (a) and cumulative survival (b) of *Euvola ziczac* in bottom culture (vertical bars represent the standard deviations of the values).

for the scallop *Euvola ziczac* may be obtained. Thus, the size range in adults located on natural banks is between 65 and 95 cm (Himmelman and Lodeiros, unpublished data), and sizes for individuals reared both in corrals (73 mm) and in cages (70 mm) were within this size interval. These sizes of scallop had wet muscle weights of 7–8 g, which are considered excellent for scallop commercialization (Dore 1991).

The rate of growth observed in this study (approx. 0.16 mm d^{-1}) was similar to that observed in *Euvola ziczac* (approx. 0.15 mm d^{-1}) for Velez et al. (1995) in the same locality, for a similar period of year (70% of the same period) and in the same period of 190 days, but with a higher initial high density (64 individuals m^{-2}) than in this study (15 individuals m^{-2}). These similar growth rates, despite the different densities in both studies, suggest that the growth observed in this study was not more influenced by the density used. This also suggests that the bottom culture productions of this species can be increased with the use of higher densities in the methods studied.

The high escape rate of individuals with the barrier-free method led to the discontinuation of this method. This suggests that *Euvola ziczac* has a high dispersion capacity, which would lead to a low recovery rate of the stock originally used for cultivation with no barriers. Therefore, we considered that it is necessary to develop a new experiment with a more adequate scale before suggesting the use of this barrier-free method. In any case, in other countries, such as Canada, Japan, and France, the use of the barrier-free bottom culture method in more adequate scales had a low recovery rate of the initial stock because of the high escape rates of scallops (Wildish et al. 1988, Aoyama 1989, Cliche et al. 1994, Dao et al. 1995). Nevertheless, Wang et al. (1992) showed that even when the recovery rate of the initial bottom stock was on the order of 54%, the low production costs exerted an influence on the high profitability of scallop cultivation of *Chlamys farreri*. In our case, the recovery rate of individuals with the barrier-free method was 16%. This may be considered as very low if we take into account that it was obtained after only 30 study days. This escape capacity was also evident in the corrals where, despite 1-m high barriers, escape gradually increased until the end of the study (36% escape). Furthermore, it was observed that some specimens cultured with this method, when unintentionally disturbed for the purpose of taking samples, showed a clearly evident capacity to escape beyond the 1-m high barriers. In these observations, we noted the increase in the vertical displacement capacity of *Euvola ziczac* as size increases. However, we do not exclude the possibility of the increase in the rate of depredation by some fish, octopus, and crab decapods during the time of the experiment. Nevertheless, this phenomenon was not noted in the course of our frequent observations.

At the end of the study, the cage-reared individuals presented a significantly lower survival rate than those reared in corrals. In the cages, greater protection from predators was expected because of the presence of netting on all sides that, theoretically, would impede their entrance of the same. In the cages, however, several fragmented shells were collected, a fact that indicated the action of predators. For this reason, a detailed search was conducted, and the presence of decapod crab juveniles *Calappa cinerea* was discovered. These had gone unnoticed until that point because of their strategy of burying themselves in the substrata. This decapod has strong chela that allow it to fragment *Euvola ziczac* shell, judging by the condition of the shells. This ability has also been noted in the species *Calappa ocellata*, as a result of its preying action on the bivalve *Brachidontes domingensis* (Hughes and Elner 1989). This suggests that the decapod *C. cinerea* apparently entered the cages at its juvenile stage, when the opening in the mesh still made this possible, so that it was also able to take advantage of the protection afforded by the cage. This situation helped avoid competition for food and being preyed upon. One observation that supports this hypothesis is that in the corrals, where there was no upper netting, the dead individuals of *Euvola ziczac* showed no shell fragmentation and nor were any detected *C. cinerea*. These observations differ from those for the cultivation of temperate water scallop species where the use of nets substantially decreased predation (Morgan et al. 1980, Quayle and Newkirk, 1990).

Because this study was conducted in a certain season of the year, possible biocontrol of decapod *C. cinerea* juveniles may not be present throughout the year. Furthermore, one of the predators that may possibly exert a dramatic effect on scallop survival under

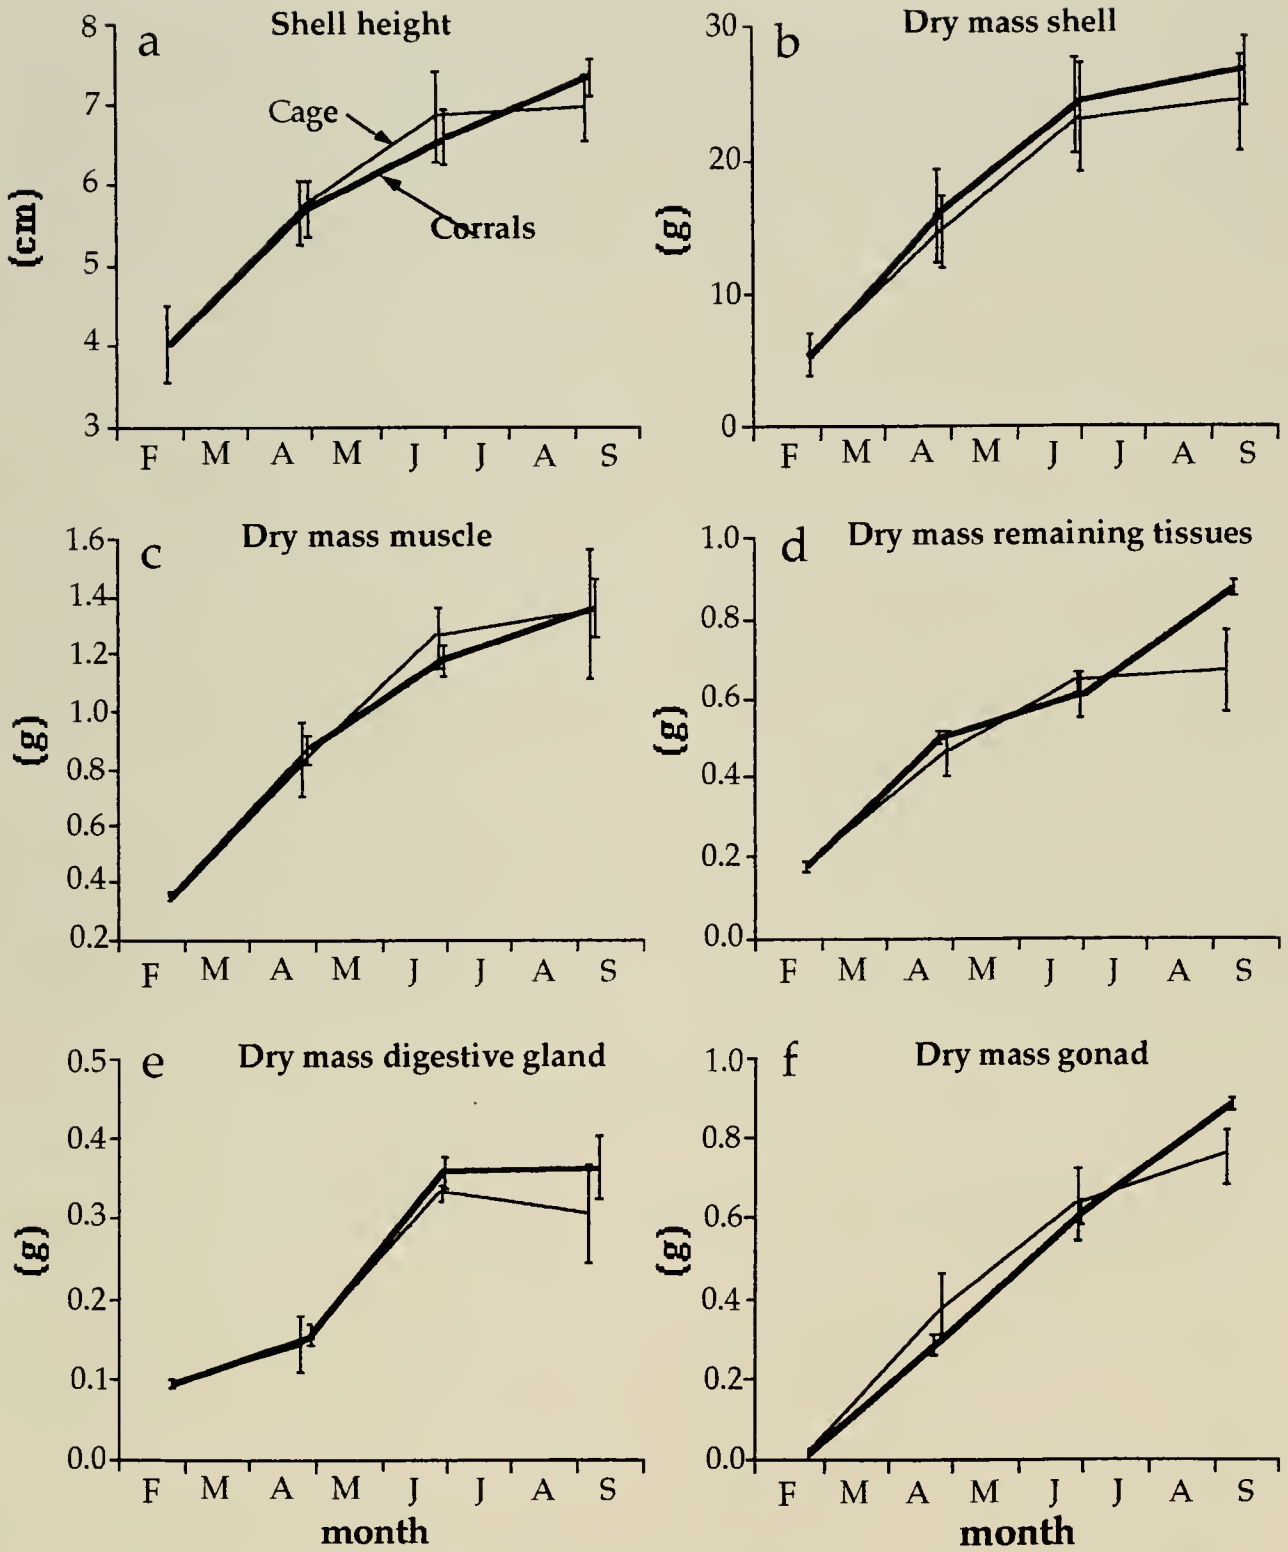

Figure 4. Growth in shell height (a) and dry mass of the shell (b) muscle (c), remaining soft tissues (d), digestive gland (e), and gonad (f) of the cultivated specimens of *Euvola ziczac* from bottom culture (vertical bars represent the standard deviations of the values).

bottom culture conditions, as noted on natural scallop banks, are the cephalopods *Octopus* spp. (Freites, personal observations). Nevertheless, despite the fact that the period of greatest influence by these predators fell within the experimental period of this study (from June to September), they were not observed. For this reason, in future studies aimed at determining the effect of predators on the survival of bivalves in corrals, it is advisable to cover different periods or seasons of the year.

Also, in the Golfo de Cariaco, hanging culture of these bivalves does not guarantee a lesser impact of predation compared to some

temperate water species (Quayle and Newkirk 1990, Hickman 1992). This is because of the recruitment of some predatory decapod and gastropod species during their planktonic larval stage, which allows them to gain access to the hanging baskets. Once inside these baskets, if uncontrolled, their growth is so fast that, in some cases, they have caused substantial mortality rates (>60%) in the cultivation of several bivalve species with culture potential, including *Euvola ziczac* (Freites et al. 1995, Freites et al. 2000), *Pinna carnea* (Narvaéz 1999) and pearl oyster *Pinctada imbricata* (Pico D., unpublished data).

The growth pattern for the corral and cage-reared individuals was similar, except in the latter sampling period, when the cage-reared individuals showed lower growth rates. These differences may not be attributable to a differential colonization by fouling organisms in nets of the enclosures or on shell that may, in the long term, affect food availability for the scallops, because the nets in both enclosures were cleaned throughout the experimental period because of the action of "grazing" of some fish and benthonic invertebrates on the net of the corrals and cage (personal observation), and because virtually no organisms colonized the shells of scallops in both enclosure, probably because the scallops were usually recessed in the sand. This together with maintaining the same density of individuals in the enclosures suggests that food availability was not a factor in the decreased growth observed in the cages.

One possible explanation is based on the fact that, as the *Euvola ziczac* individuals reared in cages increased in size and even when new *C. cinerea* decapod recruits were observed, they were physically unable to prey on the scallop because of the larger, more resilient shell, as evidenced by the subsequent lack of fractured shells. We do not rule out the fact, however, that the decapod juveniles may cause some disturbance leading to a defensive behavior, so that the bivalves close their valves, thus restricting filtration time and, consequently, affecting growth.

As we have seen earlier, the growth of juvenile scallops reared in the two types of enclosures may not be used as a selection criterion for recommending the use of dismissal of one of these two types of enclosures studied, particularly if we take into account that at the end of the experimental period, no significant differences were noted in muscle weight. Survival, however, may be used as a selection criteria, because, in the case of corrals, the rate was 27% higher. This difference would significantly affect the production level of the culture in favor of corrals. Furthermore, corrals involve a lower investment cost, and it is likely that operational costs would also be lower, because of a need for less material to construct the enclosure, and while seeding, supervision and harvesting tasks are easier. Taking the above into account, the use of corral-type enclosures is advisable, with a height of over 1 meter, to minimize escape.

Finally, during this study, an average growth rate of 6 mm month^{-1} was found. This is high if we compare it to growth rates of other scallop species of commercial importance, such as *Pecten maximus* (2 mm month^{-1}), *P. sulsicostatus* (2 mm month^{-1}), *P. albicans* (3 mm month^{-1}), and *P. novaezelandiae* (4 mm month^{-1}) (Mottet 1979). Only *Amusium balloti* (Williams and Dredge 1981), *Chlamys purpuratus* (DiSalvo et al. 1984), and *Argopecten circularis* (Felix-Pico 1991) scallops attained similar rates of growth. In this manner, the growth rate of bottom-reared *Euvola ziczac*, its survival and relatively low cost with this culture method (Ventilla 1982) offer clear possibilities for further investigations in the development of commercial culture of this species.

ALLOZYME AND BIOCHEMICAL VARIATION AT THE OCTOPINE DEHYDROGENASE LOCUS IN THE SCALLOP *EUVOLA ZICZAC*

ABSTRACT High activities of octopine dehydrogenase (Odh) in the adductor muscle of bivalve molluscs are associated with a dependence on anaerobic glycolysis during swimming. The Odh locus is polymorphic in the scallop *Euvola ziczac*. Estimated apparent Odh K_ms for arginine were not different among nine Odh genotypes: however, K_ms for pyruvate differed significantly ($P < 0.001$) between heterozygous and homozygous scallops. The estimated apparent K_m values of Odh for arginine and pyruvate are dependent on their respective cosubstrate concentrations. Possible mechanisms for this overdominance include null alleles, aneuploidy, and higher fitness of the heterozygous. Our data suggest that heterozygous superiority in fitness is the most likely explanation for the apparent overdominance at the *Odh* locus.

KEY WORDS: Arginine, bivalves, molluscs, octopine dehydrogenase, overdominance, pyruvate, scallops

INTRODUCTION

Numerous studies demonstrate how allozymes influence various components of fitness. For example, allozymes differ in their catalytic properties, including kinetic parameters (K_m and V_{max}), and heterozygous genotypes may show overdominance (exceeding the two corresponding homozygous genotypes) (Sarver et al. 1992); be intermediate in catalytic efficiency between homozygous genotypes (Hoffmann 1981, 1983); or exhibit dominance, having catalytic efficiencies similar to the most efficient genotype (Hillbish and Koehn 1985; Nirchio et al. 1991).

Allozyme heterozygosity and growth rate are positively correlated in many bivalve species (Beaumont and Zouros 1991; Zouros et al. 1992; Hedgecock et al. 1996). Higher levels of heterozygosity are associated with a lower basal metabolic rate that allows heterozygous individuals to devote more of their aerobic scope to growth and reproduction (after meeting basal requirements) (Koehn and Shumway, 1982). Recently, Hedgecock et al. (1996) found in the Pacific oyster *Crassostrea gigas* (Thunberg) that not only are oxygen consumption rates lower for hybrid compared with the inbred larvae, but also the net efficiency of protein synthesis is much higher for the hybrids. Several authors (Garton et al. 1984; Rodhouse et al. 1986; Volckaert and Zouros 1989) have suggested that organisms use this energy surplus for functions that increase fitness. In sedentary molluscs such as mussels and oysters, metabolic energy would be better invested in growth during the juvenile stages and in reproduction in adults. However, scallops are active bivalves that avoid predation by vigorous swimming; thus, selection of an allozyme could result in an increased locomotion capacity.

Scallops display sudden bursts of muscle activity, initially sustained by arginine phosphate breakdown, followed by the activation of glycolytic pathways that result in rising levels of octopine (Chih and Ellington 1983; Bricelj and Shumway 1991). Octopine is produced by the reductive condensation of arginine and pyruvate catalysed by octopine dehydrogenase (Odh, EC 1.5.1.11), in the presence of NADH. High activities of Odh occur in the adductor muscles of scallops (Chih and Ellington 1983; Alfonsi et al. 1995). The advantage of octopine formation in adductor muscles may be that oxidation of NADH removes arginine and thereby facilitates the formation of ATP from arginine phosphate.

The energy needs among molluscs vary, as scallops, which swim, require higher instantaneous rates of ATP production than sedentary bivalves such as mussels and oysters. Phosphoarginine is the principal fuel during valve snapping, and octopine accumulates during the subsequent recovery phase under functional anaerobiosis (Bricelj and Shumway 1991). Genetic effects on glycolitic ATP production are correlated with increased ability for burst activity in pectinids. Volckaert and Zouros (1989) found in the scallop *Placopecten magellanicus* (Gmelin) that heterozygosity and octopine accumulation after burst activity are correlated. The degree of heterozygosity and the maximal activity of pyruvate kinase and Odh are positively correlated in the adductor muscle of the scallop *Euvola ziczac* (Alfonsi et al. 1995).

In scallops, the primary function of Odh is to maintain the redox balance of the muscle during exhaustive exercise. The present study was designed to determine whether allozymes of Odh, which is polymorphic (Coronado et al. 1991), differ in catalytic properties. We determined this by measuring the apparent K_m of Odh in the scallop, *E. ziczac*, under varying concentrations of pyruvate and arginine.

MATERIALS AND METHODS

Adult scallops, *E. ziczac* ($n = 103$), were collected in 1998 during their sexual resting period from the waters of the Gulf of Cariaco (Chacopatica) on the northeastern coast of Venezuela (10°30′10″N, 64°13′06″W). They were maintained in running aerated seawater.

To determine the genotype at the Odh locus, the adductor muscle from each individual was excised, minced, and centrifuged, and the supernatant was analyzed by horizontal 12% starch gel electrophoresis. The activity of Odh was identified using the staining procedures described by Morizot and Schmidt (1990). Allelic variants were designated by letters, with "a" being always the most anodic. To prepare the enzyme extracts, the frozen adductor muscle of each specimen was chopped and homogenized in 20% w/v cold 50 mM imidazole-HCl buffer in ice, pH 7.5, with 2 mM ethylenediaminetetra-acetic acid. The homogenized tissue was

centrifuged at 27,000 *g* for 20 min at 4 °C. Solid ammonium sulphate was added to the supernatant to reach 70% saturation. The resulting suspension was stirred at 4 °C for 30 min and then centrifuged at 20,000 *g* for 20 min. The pellet was dissolved in a small volume of the homogenizing medium, applied to a Sephadex G-100 column equilibrated with 50 mM Tris-HCl (pH 7.6) at 24 °C, and eluted with the same buffer. The eluted fraction with highest Odh activity was used for kinetic analyses.

Odh activity was measured by recording changes in optical density (OD; 365 nm) that were caused by the oxidation of NADH. Reactions were run using 25 µL of the enzyme preparations in 1.25 mL of incubation mixture. The routine enzyme assay for maximal activity was 0.2 mM NADH, 2.5 mM pyruvate, and 5.0 mM arginine in a 50 mM imidazole buffer at pH 7.5. All of the assays were run at 24 °C. The enzyme activity was expressed as spectrophotometric units (OD). Maximal activity was recorded between pH 6.0 and 7.5 in pilot enzymatic assays.

Odh followed Michaelis-Menten kinetics for both arginine and pyruvate, at saturation concentrations of the other substrate and of NADH. Substrate inhibition by pyruvate was observed at concentrations over 2.5 mM. Accordingly, the apparent Michaelis constants (apparent K_m) for the substrates arginine and pyruvate were estimated from the Michaelis-Menten equation, according to Churchill and Livingstone (1989):

$$\text{Estimated apparent } K_m = (V_{max}/V) - 1/S$$

where *V* represents the initial reaction velocity at either a pyruvate or arginine subsaturating concentration, when the respective cosubstrate was at a saturating level. Before applying this formula, the maximal velocity was calculated from the Lineweaver-Burke plots (Segel 1975), in which the concentration of one substrate (A) was varied and the concentration of the other substrate (B) kept constant. The data were fitted to the following equation:

$$1/V = K_m^B/V_{max} (1 + K_m^A/A)\ 1/B + 1/V_{max}$$

The initial velocity was recorded against the pyruvate concentration (0.10, 0.20, 0.83, and 2.50 mM) at fixed arginine concentrations (0.5, 1.5, 3.0, and 5.0 mM). The inverse of the initial velocity (1/V) was plotted against the inverse of the pyruvate concentration (1/S) for each arginine concentration. The Y intercepts of the Lineweaver-Burke lines estimated by linear regression analysis were plotted against the inverse of arginine concentration. The maximal velocity was determined from the value of the resulting Y intercept, which was essentially similar to that estimated by the routine enzyme assay. Likewise, the data were plotted as a function of the arginine (0.5, 1.5, 3.0, and 5.0 mM) concentration. The V_{max} value estimated agrees with that obtained using varying concentrations of pyruvate at fixed concentrations of arginine. Substrate inhibition of V_{max} was observed for pyruvate concentrations over 2.5 mM at each arginine concentration.

Deviations from expected values of allele frequency for Hardy-Weinberg equilibrium were tested by using a Chi-square analysis. The deficiency or excess of heterozygotes (analyzed by the F statistic) and the effective number of alleles at this locus (N_e, the reciprocal of the sum of squares of the allele frequencies) were calculated by using the statistical program Genes in Populations, version 2 (Perkins and Paul 1995).

RESULTS AND DISCUSSION

The sample of 103 individuals from the population of Chacopatica contained nine Odh genotypes: c/c, d/d, e/e, b/c, c/d, c/e, c/f, d/e, and d/f, determined by five alleles Odh^b, Odh^c, Odh^d, Odh^e, and Odh^f. Because genotypes that include alleles a and b are very rare (Table 1), it was not possible to obtain sufficient samples to study their catalytic properties of these rare alleles. Allele frequencies have been stable since the first sample was examined in 1984. All three samples were in Hardy-Weinberg equilibrium. Heterozygote superiority probably provides the best explanation for the maintenance of the polymorphism.

Apparent K_m for arginine and pyruvate were related to variations in the concentrations of the respective cosubstrates, because K_m decreased as the concentration of cosubstrate increased (Table 2). This suggests a mechanism that favors the formation of octopine when the concentration of the two substrates increases simultaneously, as is seen in active individuals. The availability of arginine and pyruvate could be the two limiting factors in the regulation of Odh activity for maximal glycolytic capacity during the escape response and recuperation of *E. ziczac*. In addition, specific genetic influences affect the regulatory properties of the enzyme by acting on their relative substrate affinities.

Results for the K_m of pyruvate and arginine at different cosubstrate concentrations were separated into two groups: homozygotes and heterozygotes. Table 3 indicates no significant differences for the K_m of arginine (pyruvate as cosubstrate) ($F = 0.017$; $P > 0.05$), whereas highly significant differences were detected between homozygotes and heterozygotes for the K_m of pyruvate (arginine as cosubstrate) ($F = 29.33$; $P < 0.001$). These results indicate that the affinity of the Odh enzyme for pyruvate was predominantly greater in heterozygous than in homozygous individuals. Similar results were observed by Walsh (1981) for three phenotypes of Odh in the anemone *Metridium senile* (L.), in which the heterozygotes showed a higher affinity for pyruvate. Sarver et al. (1992) mea-

sured specific Odh activities in a large number of individuals of the mussel *Mytilus trossulus* Gould for Odh and found that the mean Odh activity was greater in heterozygotes than homozygotes.

Multiple range analysis (least-significant difference) indicate three groups in increasing order of K_m: (1) d/f, e/e, d/e, c/d, and c/e; (2) c/d, c/e, and c/c; and (3) d/d. Genotypes c/d and c/e belonged to the groups with higher and medium affinities [1] and [2], Table 3). By increasing Odh affinity for pyruvate, heterozygous individuals could enhance the ability of the muscle to maintain the NADH/NAD^+ redox balance during the glycolytic flux which can occur during high-intensity muscle work. This affinity would be particularly useful during the initial phase of glycolysis when pyruvate concentration is low and arginine levels begin rising (arginine phosphate pool is depleted). Moreover, the shunting of pyruvate to mitochondrial metabolism or cytoplasmic synthesis of alanine could be inhibited to rapidly meet the energy demands under functional anaerobiosis of the contracting fibers. On the other hand, it appears that arginine does not represent a control or limiting factor for the anaerobic glycolitic capacity for the fast muscle contraction of *E. ziczac*. This assertion, however, does not exclude the possibility of other genetic influences on the enzymatic conversion of arginine into arginine phosphate, which would assure a faster recuperation after a burst exercise.

Heterozygotes show an apparent overdominance in K_m for pyruvate that may be a fitness component if the concentration of pyruvate is low. Apparent overdominance (heterozygous genotypes are phenotypically superior to homozygous genotypes), in fitness components such as growth, viability, and fecundity, has been observed in many species of marine bivalves (Sarver et al. 1992). Possible explanations for overdominance, as well as the commonly reported deficiencies of heterozygotes, include null alleles (Foltz 1986) and aneuploidy (Thiriot-Quievreux et al. 1988). Several studies of allozyme inheritance have found substantially higher frequencies of null alleles in bivalves than found in other organisms, suggesting that null alleles or segmental aneuploidy may play a role in the apparently lower fitness of allozyme heterozygotes (Gaffney 1994). Null alleles or missing chromosomes (and therefore missing alleles) could contribute to fitness advantages of heterozygotes. In *Mytilus edulis* (L.), Hoare and Beaumont (1995) found not only heterozygotes, but also homozygotes for a null Odh allele. We believe this situation unlikely to occur an active species, such as *E. ziczac*.

N is the number of animals examined. Means are different ($P < 0.001$).

Considering an alternate explanation of heterozygote superiority in fitness or other phenotypic attributes to explain our results, there are two possible scenarios, as follows.

(1) Individuals that appear single banded (homozygous), which were numerous in our sample, may really be heterozygous (active/null alleles); if so, we would expect a bimodal distribution, with a resulting higher variance of activity in homozygous compared with heterozygous. However, this was not the case for our samples of *E. ziczac* (see Table 3).

(2) Results obtained in the analysis of other enzymes (pyruvate kinase, glucose 6-phosphate dehydrogenase, isocitrate dehydrogenase, and malate dehydrogenase) in *E. ziczac* indicate that their specific activity is correlated positively with heterozygosity. Because the Odh activity in homozygotes and heterozygotes scallops increases with heterozygosity at multiple loci, it seems highly unlikely that null alleles (or missing chromosomes) would occur at all of these loci (Alfonsi et al. 1995).

Therefore, our results can be best explained by assuming an overdominance at the Odh locus, which could enable the heterozygotes to increase their ability to escape from predators.

In conclusion, the pyruvate affinity of the adductor muscle Odh allozyme in *E. ziczac* appears to be a catalytic target upon which genetic influences act to determine the tissue's capability for maintaining a steady NADH/NAD ratio, that would support the rate of anaerobic glycolysis at the burst working muscle, such as the

sudden escape behavior commonly observed among scallops when they flee from predators. During routine work, we have observed that *E. ziczac* scallops are easily induced to vigorously snap their valves (swimming) when approached by gastropods, crabs, starfish, and human divers. This predator-avoidance behavior may be repeated for several minutes before entering in a variable resting period. However, the nature of the relationship that exists between the capability to sustain muscle contraction in response to predatory stimulus and the Odh genotypic variants in *E. ziczac* is not clear.

Finally, further research is required on some biochemical and physiological events associated with activity in different genotypic variants of *E. ziczac*, both under laboratory bioassays and field work conditions, because predation is a significant component in the life history of adult scallops, we are currently searching for a possible relationship between the escape reaction and the different genotypes, and because polymorphism at the Odh locus in *E. ziczac* seems to be important for understanding genetic variation in molluscs, we are also searching for the presence of polymorphism in other, sedentary and motile, species of molluscs. Additionally, we are examining strombine and alanopine dehydrogenase (which also serve as hydrogen and carbon sinks in maintaining redox balance) in several species of molluscs during anaerobic metabolism, for possible polymorphisms and their maintenance mechanisms.

ENVIRONMENT AND POPULATION ORIGIN EFFECTS ON FIRST SEXUAL MATURITY OF CATARINA SCALLOP, *ARGOPECTEN VENTRICOSUS* (SOWERBY II, 1842).

PEDRO CRUZ, CARMEN RODRIGUEZ-JARAMILLO, AND ANA M. IBARRA

ABSTRACT Two populations of catarina scallop, and their cross (F1), were evaluated for the age at first sexual maturity, and for their gonadal development in both populations' native environments. All experimental groups were hatchery produced. Differences in mean gonad index (MGI) were seen between the different environments. In Bahia Magdalena, a site characterized by high productivity and lower average water temperatures, the MGI was higher than for scallops grown in Bahia Concepción, a bay with lower productivity and higher average water temperatures. Differences in age and size at first sexual maturity, defined as those when 50% of the scallops in any group were sexually mature, were seen between the populations when grown at Bahia Magdalena but not when grown at Bahia Concepción. At Bahia Concepción, none of the groups had reached their first sexual maturation after the experimental period of 7 mo. At Bahia Magdalena, the Magdalena population and the F1 reached sexual maturity at an early age of 4 mo, whereas the Concepción population reached maturity when 5 mo old. Also for the Bahia Magdalena environment, the gonad index (GI) estimated at first sexual maturity for the Magdalena population and the F1 was significantly higher than that estimated for the Concepción population at that same age. There were no significant differences in GI values when the groups were grown at Bahia Concepción. The differences between populations in age at first sexual maturity suggest that a triggering mechanism exists in catarina scallop for the initiation of sexual maturation, whereas the differences between environments suggest that regardless of that mechanism, environmental conditions have a significant role in further maturation processes.

KEY WORDS: *Argopecten ventricosus*, environment, gonad index, populations, maturation

INTRODUCTION

The catarina scallop, *Argopecten ventricosus* (Sowerby II, 1842), which is a functional hermaphrodite species, is an important fishery and aquaculture resource on both coasts of the Baja California Peninsula, Mexico. The geography of the peninsula results in this species distributing and growing in different environmental conditions: semitropical to temperate on the Pacific Ocean side and tropical on the Gulf of California side. Because of this, as well as the presumed isolation caused by the Peninsula barrier itself, natural populations existing on both sides are expected to be genetically different, that is, to have evolved differently in response to environmental conditions on each side. In fact, we have demonstrated that there are differences between these two populations in growth and survival (Cruz and Ibarra 1997, Cruz et al. 1998).

An additional important trait to compare in populations on both sides of the peninsula is the age and size at which each population reaches its first sexual maturity. It has been stated that the reproductive cycle of scallops is a genetically controlled response to environmental conditions (Sastry 1970, Sastry 1979, cited by Barber and Blake 1991), which depends on the optimum interactions between exogenous and endogenous factors. When the appropriate combination of exogenous and endogenous factors occurs, a minimum age (or size) has to be reached before the beginning of gametogenesis (Barber and Blake 1991). Differences in the onset of sexual maturity and reproductive cycle have already been reported for other bivalve species (Dalton and Menzel 1983, Knaub and Eversole 1988, Barber et al. 1991, Mackie and Ansell 1993). Among different bivalves studied simultaneously at different sites, or through transplantation, there are differences in the onset of gametogenesis (Newell et al. 1982, Barber and Blake 1983, Walker and Heffernan 1994), spawning time (Brousseau 1987, Emmett et al. 1987, Paulet et al. 1988), fecundity (Bricelj et al. 1987), and gametogenic cycle (Wilson 1987, Thorarinsdóttir 1993, Sbrenna and Campioni 1994). Some of the previously reported differences are not necessarily caused by genetic factors but by different environmental conditions at each site studied.

Different studies with catarina scallop have been performed regarding sexual maturation and gametogenic cycles (Baqueiro et al. 1981, Tripp-Quezada 1985, Villalejo-Fuerte 1992, Félix-Pico 1993, Villalejo-Fuerte and Ochoa-Báez 1993). However, differences between populations in age at first sexual maturity or in the effects of different environments on gametogenic cycles and maturation have not been investigated.

In this study, we evaluated the onset of first sexual maturity and the gametogenic cycles for two populations of catarina scallop and their cross (F1). The two populations were Concepción in Bahia Concepción on the Gulf of California side of the Baja California, and Magdalena in Bahia Magdalena on the Pacific Ocean side of the Baja California peninsula. All groups, Magdalena, Concepción, and their F1s, were simultaneously evaluated in both environments.

MATERIALS AND METHODS

Populations and F1

Spawners used, conformation of the experimental groups, and larvae rearing have been described by Cruz and Ibarra (1997). In summary, four groups were produced by mass spawning; Magdalena, Concepción, and both reciprocal F1s. At a spat size of 1.5 cm length and 2.5 mo old, 9 (pseudo) replicates, each with 100 scallop spats, were formed within each group by randomly sampling 900 spats from the total group pool.

Grow-Out

The spat contained within each of the nine replicates per group were simultaneously transported to each of the experimental field areas, Bahia Magdalena and Bahia Concepción, where they were maintained for 5 mo. At each site, the scallops contained in each replicate were kept in a Nestier tray suspended from a long-line for 45 days and then were transferred to bottom culture to avoid position effects on growth caused by water temperature stratification. Nestier trays were attached to a metal structure anchored to the bottom. Maintenance was performed monthly. Densities were the same for all replicates within groups and in both environments (Cruz et al. 1998).

Gonad Sampling and Histology Analysis

Sampling for gonad tissue began after 1.5 mo of grow-out, at 4 mo age. Three individuals were sampled per replicate (27 per group) at ages 4, 5, 6, and 7 mo. Samples were fixed in Davidson's fixative and were preserved in 70% alcohol. The hematoxylin-eosin staining technique was used. Sexual maturity was evaluated with a modified Villalejo-Fuerte (1992) scale for this hermaphrodite scallop, where seven stages are included for the female portion of the gonad (Stage 0 = undifferentiated or virginal; Stage I = resting; Stage II = start of gametogenesis; Stage III = advanced gametogenesis; Stage IV = maturity; Stage V = spawned; Stage VI = postspawned).

Age-Size at First Sexual Maturity

Age and size at first maturity were established by a different criterion than that commonly used when populations are evaluated following a field-born cohort (Nikolsky 1969). Under that methodology, age-size at first maturity is estimated when the cumulative frequency of mature individuals reaches 50% in the cohort. Field-born individuals of a population are of different ages because spawning of the whole population usually last from days to weeks. In the present study, all individuals were the same age. Therefore, in this study, age and size at first sexual maturity were defined as the age when 50% of the organisms within any group were in the "maturity" gonadal stage, or Stage IV as defined above, or when the sum of individuals in Stage IV (maturity), Stage V (spawn), and Stage VI (post-spawn) was ≥ 50%. Only the female gonad portion was used for the establishment of the age and size at sexual maturity.

Gonad Indices

Gonad indices (GIs) were calculated for each replicate within each group based on a calculation by Seed (1976) by using the number of individuals and the stage at each age (4, 5, 6, and 7 mo) to find a GI at age for each group as follows:

$$GI_{ijk} = [(0*N_0) + (1*N_I) + (2*N_{II}) + (3*N_{III}) + (4*N_{IV}) + (5*N_V) + (6*N_{VI})]/N_{tot(ijk)}$$

where GI_{ijk} is the GI for replicate i (i = 1,2,3,...9), of the group j (j = 1,2,3), in the environment k (k = 1,2); $N_{subscript}$ is the number of individuals in that gonadal stage for replicate i; and $N_{tot(ijk)}$ is the total number of individuals in that replicate of that group in that environment.

Statistical Analyses

The GIs estimated for each replicate within the groups were analyzed by a complete two-factor, Model I, analysis of variance, where age was taken into consideration as a covariable. After establishing the lack of differences between the reciprocal F1s ($P > 0.05$), for all further analysis the F1s were pooled into what is defined as the F1 between these two populations. The effects of group (Magdalena, Concepción, and F1), environment (Bahia Magdalena and Bahia Concepción), and their interaction on GI were analyzed. Effects means were compared with a Tukey test, setting $\alpha = 0.05$. Additionally, at the age when first sexual maturation was observed, as defined above, a second partial Model I analysis of variance was made. This was performed to establish the effect of groups and environments on GIs at the age of first sexual maturity and to find out whether there was a group by environment interaction for GI. All statistical analyses were performed using a computer software (Statistica, version 5; StatSoft, Inc.; Tulsa, OK), and significance for all analyses was set to $P < 0.05$.

RESULTS

First Sexual Maturity

At Bahia Magdalena, the age at first sexual maturity (Stage IV) for the Magdalena population was 4 mo. However, at this age, which corresponds to the first sampling time during grow-out (1.5 mo of grow-out), 56% of the individuals were scored as matured, but 9% were spawned, and 13% postspawned. This indicated that first sexual maturity occurred slightly before this time. Shell height at 4 mo of age was 20.0 mm (SD ± 0.88 mm). At this same age, the F1 also reached sexual maturity, as defined in this study, since it had 41% individuals in the maturity stage, 19% spawned, and 5% postspawned (Table 1). Shell height was 21.2 mm (SD ± 0.85 mm). At the age of 4 mo, the Concepción population had no mature or spawned individuals, but 4% were postspawned (Table 1). At 5 mo of age, the Concepción population had 75% mature individuals, reaching sexual maturity (Fig. 1) at a shell height of 32.9 mm (SD ± 1.34 mm).

At Bahia Concepción, sexual maturity was not reached by any group during the experimental period (Fig. 1). Although sexual maturity was not detected in this environment, a differential pattern between groups was evident from 5 mo to the end of the study: a larger percentage of individuals from the Magdalena population and the F1 were postspawned than the percentages seen for the Concepción population. Also, at 7 mo of age, corresponding to the last sampling date, 16% of the individuals within the Magdalena group and 4% of the F1 were already matured, whereas within the Concepción group there were no mature, spawned, or postspawned individuals (Fig. 1).

GIs

Both main effects (group and environment) were significant for both analyses, the whole grow-out period and the age (4 mo) at sexual maturity in the Magdalena population and the F1. There was no interaction between groups and environments (Table 2). For the whole grow-out period, mean GIs (MGIs) for all groups at Bahia Concepción (MGI 1.63) were significantly less than those at Bahia Magdalena (MGI 3.72) (Table 3). These MGI values indi-

TABLE 1.

Frequencies (in percentages), of *A. ventricosus* at 4 mo of age, in each gametogenic stage within each experimental group when grown at Bahia Magdalena and Bahia Concepción.

	Bahia Magdalena			Bahia Concepcíon		
Stage	Magdalena Population	F1	Concepción Population	Magdalena Population	F1	Concepción Population
0 Undifferentiated	0	5	22	75	89	100
I Resting	0	5	0	25	6	0
II Initial gametogenesis	0	5	48	0	5	0
III Advanced gametogenesis	22	17	26	0	0	0
IV Maturity	56[a]	41[a]	0	0	0	0
V Spawned	9	19	0	0	0	0
VI Postspawned	13	5	4	0	0	0

[a] Indicates whether sexual maturity of female gonad portion was reached for that group at this age.

cated that, over the grow-out period, scallops at Bahia Magdalena were between the advanced gametogenesis (Stage III) and spawned (Stage V) stages, whereas those at Bahia Concepción were between resting (Stage I) and initial (Stage II) gametogenic stages. Within environments and for the whole grow-out period, there were significant differences between groups only when grown at Bahia Magdalena, where the two populations were different, and the F1 was in an intermediate maturity stage, which is not different from either population. The largest GI was that of the Magdalena population (GI 4.02), followed by the F1 (GI 3.81) and the Concepción population (GI 3.33) (Table 3).

At 4 mo of age, when sexual maturity had occurred, the MGI at Bahia Concepción was lower (MGI 0.5) than that at Bahia Magdalena (MGI 3.17). There were significant differences between groups only in Bahia Magdalena, with no significant differences in GI between the Magdalena population (GI 4.08) and the F1 (GI 3.57), whereas the Concepción population had the lowest GI (GI 1.85) (Table 3). At Bahia Concepción, GIs were not

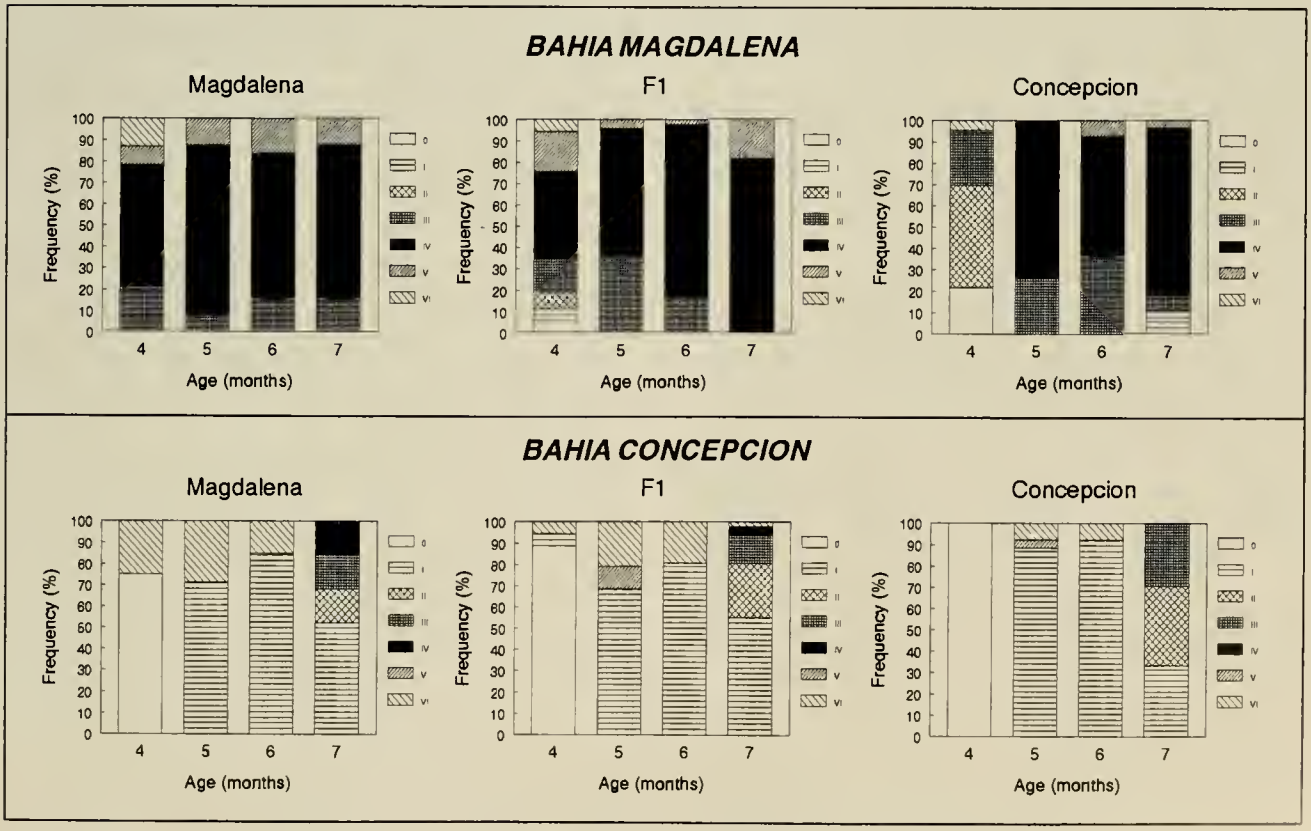

Figure. 1. Frequencies of gonadal developmental stages in *A. ventricosus* at the ages of 4, 5, 6, and 7 mo, for each experimental group at each environment. Stage 0 = undifferentiated; Stage I = resting; Stage II = start of gametogenesis; Stage III = advanced gametogenesis; Stage IV = maturity; Stage V = spawned; and Stage VI = postspawned.

different between groups (1.0, 0.5, and 0.0, respectively, for the Magdalena population, F1, and Concepción population).

DISCUSSION

Differences between the two populations in age and size at sexual maturity were clearly evident when grown at Bahia Magdalena but not at Bahia Concepción. At Bahia Concepción, sexual maturity was not reached by any of the groups. However, at 7 mo, some mature individuals were already present for the Magdalena population, but not for the Concepción population. Previous work by Villalejo-Fuerte and Ochoa-Báez (1993) indicates that the native population at Bahia Concepción reaches sexual maturity at the age of 1 y and a 58-mm shell height. For other *Argopecten* species, as for example *Argopecten irradians*, the maximum gonad weight was reported to be at 57 mm shell height (Bricelj et al. 1987), whereas for *Argopecten gibbus*, ripe individuals as small as 20 mm shell height have been reported (Miller et al. 1979). In fact, precocious individuals such as those seen in the population of *A. ventricosus* from Bahia Magdalena have only been reported for *A. gibbus*, which reaches sexual maturation when only 71 days old (see review by Barber and Blake 1991).

The failure of all groups to reach sexual maturity during our experimental period when grown at Bahia Concepción can be explained by the environmental conditions which characterize this bay: low productivity (chlorophyll-*a* 0.38–1.63 mg/m^3) and high average annual temperature (24.9 °C) with a wider range (17.7–32.1 °C) (Martínez-López and Gárate-Lizárraga 1994, Reyes-Salinas 1994). Bahia Magdalena is characterized as a more benign environment. Average temperature is 22 °C, with a small range (20–26.6 °C) (Hernández-Rivas et al. 1993), and a high chlorophyll-*a* concentration (1.5–5.1 mg/m^3) (Acosta-Ruiz and Lara-Lara 1978). Poor environmental conditions are known to affect gonad development (i.e., decreases in reproductive output seen in *Placopecten magellanicus*) (Macdonald and Thompson 1985). Barber and Blake (1991) proposed that the oocyte reabsorption seen in different species of Pectinids could be caused by unfavorable temperatures that inhibit full gonad development. This was probably the case in the Bahia Concepción population, where despite the fact that mature individuals 4–6 mo old were not detected, there were some classified as postspawned. Furthermore, rather than in the undifferentiated stage, most scallops in Bahia Concepción were in a resting stage during most of the experimental period, which could have been caused by attempted maturation followed by follicular atresia because of high temperatures and low productivity.

TABLE 3.

GIs (SD) in *A. ventricosus*, for the whole grow-out period and for the age at sexual maturity (reached when grown at Bahia Magdalena at 4 mo of age) for each environment and for each experimental group.[a]

Environment	Group	Whole grow-out period	Age 4 mo (Sexual Maturity)
Bahia Magdalena	Magdalena GI	4.02 (0.45)^{a}	4.08 (0.75)^{a}
	F1 GI	3.81 (0.62)^{ab}	3.57 (0.94)^{a}
	Concepción GI	3.33 (1.14)^{b}	1.85 (1.28)^{b}
	BM MGI	3.72 (0.81)^{A}	3.17 (1.32)^{A}
Bahia Concepción	Magdalena GI	1.81 (1.26)^{c}	1.0 (2.24)^{c}
	F1 GI	1.75 (1.30)^{c}	0.5 (1.58)^{c}
	Concepción GI	1.34 (0.96)^{c}	0.0 (0.00)^{c}
	BC MGI	1.63 (1.22)^{B}	0.5 (1.54)^{B}

MGI (SD) is the average female GI of all groups within that environment. GIs for gonad by group are given. Means with the same letter within gonad part (female or male) are not significantly different. Group means differences within environment and sex in lower case. Capital case letters for differences between environments.

The mechanism that detains the maturation process under inadequate environmental conditions is not known. However, it is known that in *A. irradians*, the regulation of the gametogenic cycle is controlled by a neurosecretory cycle with a checkpoint that seems to act as a switching mechanism, allowing or delaying oocyte growth depending on food and temperature (Barber and Blake 1991). When scallops are subjected to prolonged threshold temperatures after the neurosecretory cycle enters the neurosecretory stage (NS) corresponding to cytoplasmic growth phase (NS III) or vitellogenesis (NS IV), scallops do not regress in NS, and vacuolization of cytoplasm and lysis of oocytes can occur (Sastry, 1966a, 1968, cited by Barber and Blake 1991). Whether a similar mechanism exists in the catarina scallop is not known, but it could explain the presence of atresias in scallops when they are grown in Bahia Concepción.

The differences between populations in age at sexual maturity suggest that a genetic triggering mechanism might exist for the onset of sexual maturity in the catarina scallop. When grown in Bahia Magdalena, an environment characterized by high productivity and lower temperatures, the mechanism of early maturation in the Magdalena population and the F1 is triggered, and because the prevailing environmental conditions at this site (low temperature and abundant food), full development is reached at an early age. A suggestion that the mechanism is genetically controlled comes from the age and size at which the two populations reached their first sexual maturity. The Concepción population reached sexual maturity in this environment at least 1 mo later than the Magdalena population. Inheritance (from the Magdalena population to the F1) in the dominant fashion of an early triggering mechanism is suggested by the F1 reaching sexual maturity at the same age as the Magdalena population and by the fact that the GIs of the F1 showed no significant differences with the Magdalena population at first sexual maturity. However, the GI of the F1 group was intermediate to the GIs of the two populations for the whole grow-out period, indicating more of an additive form of inheritance for this trait. Furthermore, whereas at Bahia Concepción sexual maturity was not reached for any group in this study, at 7 mo of age there were 16% mature individuals within the

Magdalena population, but only 4% mature and 2% post spawn for the F1 (6%). Further research, with segregation studies included, is required to provide a definitive answer to the inheritance of this trait. Whereas the inheritance of reproductive traits has been suggested in other mollusk species, no study has attempted to demonstrate it at the genetic level. For example, Knaub and Eversole (1988) found that the F1 between two populations of *Mercenaria mercenaria* resembled the paternal population in some reproductive traits and the maternal population in others. Also, each of two lines of *Crassostrea virginica*, derived from two populations 5–6 generations before, still followed the reproductive pattern of their original populations (Barber and Blake 1991).

ACKNOWLEDGMENTS

We thank MAZAVI enterprise for help during field maintenance of the experimental groups, and M. Romero from SEMARNAP, Guy. A. Garcia and Jose L. Ramirez from CIBNOR for technical support during this research. This research was partially supported by CONACyT grants 720-N9204 and 1473PB to A.M. Ibarra. ABSTRACT This study describes, through monthly histological examinations of gonadal tissue samples, the reproductive cycle of *Pinna rugosa* and relates gametogenesis to temperature and photoperiod. Monthly gonadal samples were obtained from February 1993 to February 1994, in Bahía Concepción, Gulf of California, Mexico. Five stages of gonadal development were characterized: indifferent, developing, ripe, partially spawned, and spent. Histological evidence revealed hermaphroditism in 20.9% of animals sampled. Gametogenesis commenced in March, with ripe and spawning stages occurring from April to November, and no gametogenic activity occurring from December to February. From March to November, water temperature ranged from 20 °C to 31 °C, with an average range of light of 650–820 min/day. *P. rugosa* had a seasonal gametogenic cycle directly related to water temperature and photoperiod.

KEY WORDS: Reproduction, bivalve, *Pinna*, histology, Gulf of California

INTRODUCTION

The rugose pen shell, *Pinna rugosa* Sowerby, 1835, is commonly known in Mexico as "hacha" (hatchet). This bivalve is of commercial importance and supports a fishery in the northwestern area Gulf of California, Mexico. *P. rugosa* is greatly appreciated by consumers because of its tasty, large adductor muscle, commonly referred to as "callo." The pen shell fishery has been an important economic activity in Mexico for many years. Production trends, however, have drastically declined over the past years, and some populations have been depleted (Reynoso-Granados et al. 1996). Few biological studies of *P. rugosa* have been conducted (Arizpe and Félix 1986, Arizpe and Covarrubias 1987, Mazón-Suástegui and Avilés-Quevedo 1988, Ruíz-Verdugo and Cáceres-Martínez 1990, Arizpe 1995).

Documentation of the reproductive biology of *P. rugosa* in the Gulf of California is extremely scarce. Noguera and Gómez-Aguirre (1972) described the reproductive cycle of *P. rugosa* in Laz Paz Bay, B.C.S., Mexico, and they showed that gametogenesis commenced in mid-spring and that the animals spawned in late summer.

Because of the economic importance and high price obtained by the callo, efforts have recently been under way to cultivate this species. Therefore, studies of its reproductive biology are essential to achieve reproduction in a laboratory setting. This study documents the reproductive cycle of *P. rugosa* from Bahía Concepción, Gulf of California, Mexico, and examines the relationship of gametogenesis to temperature/photoperiod.

MATERIALS AND METHODS

Bahía Concepción, Mexico, is located on the western coast of the Península of Baja California, between 26°55′ and 26°30′N and 112° and 111°40′E. The bay is approximately 40 km long and 10 km in its widest part and oriented in a NW-SE direction (McFall 1968).

Monthly, between 13 and 35 specimens of rugose pen shell were collected by a scuba diver at a 2- to 8-m depth from February 1993 to February 1994. Animals were collected from a wild population located off Santispac Beach in Bahía Concepción, Gulf of California. The individuals were collected and fixed in 10% formalin solution. When the biological samples were collected, water temperature at the collection site was recorded.

The visceral mass (gonad included) was dissected from each pen shell and stored in 70% alcohol. Later, a slice of tissue of the dorsal area of the visceral mass was cut. This tissue samples were dehydrated in an ethanol series of progressive concentrations, cleared in toluene, and embedded in paraffin. Serial sections 7–9 μm thick were obtained with a rotary microtome. Preparations were stained with hematoxilyn and eosin. The gonad structure was examined under a microscope, and the sex was determined for each animal by the presence of egg or sperm in the tissue section.

Each tissue section of *P. rugosa* was categorized on the basis of the qualitative characteristics of five stages of maturation (indifferent, developing, ripe, partially spawned, and spent) as described by Villalejo-Fuerte and García-Domínguez (1998). The monthly relative frequencies of the stages of gonadal development throughout the annual cycle were obtained. This enabled the description of the reproductive cycle. The spawning season is defined as the time period containing ripe and partially spawned individuals.

To obtain a quantitative value that represents the reproductive activity, a monthly gonad index (GI) was computed (Heffernan et al. 1989) utilizing a numerical grading system. Three categories were established according to the degree of development of the gonad, with 1 = indifferent and spent, 2 = developing, and 3 = ripe and partially spawned. The monthly GI was determined by multiplying the number of specimens ascribed to each category by the category score, summing all such values, and dividing the resulting value by the total number of pen shells analyzed. The

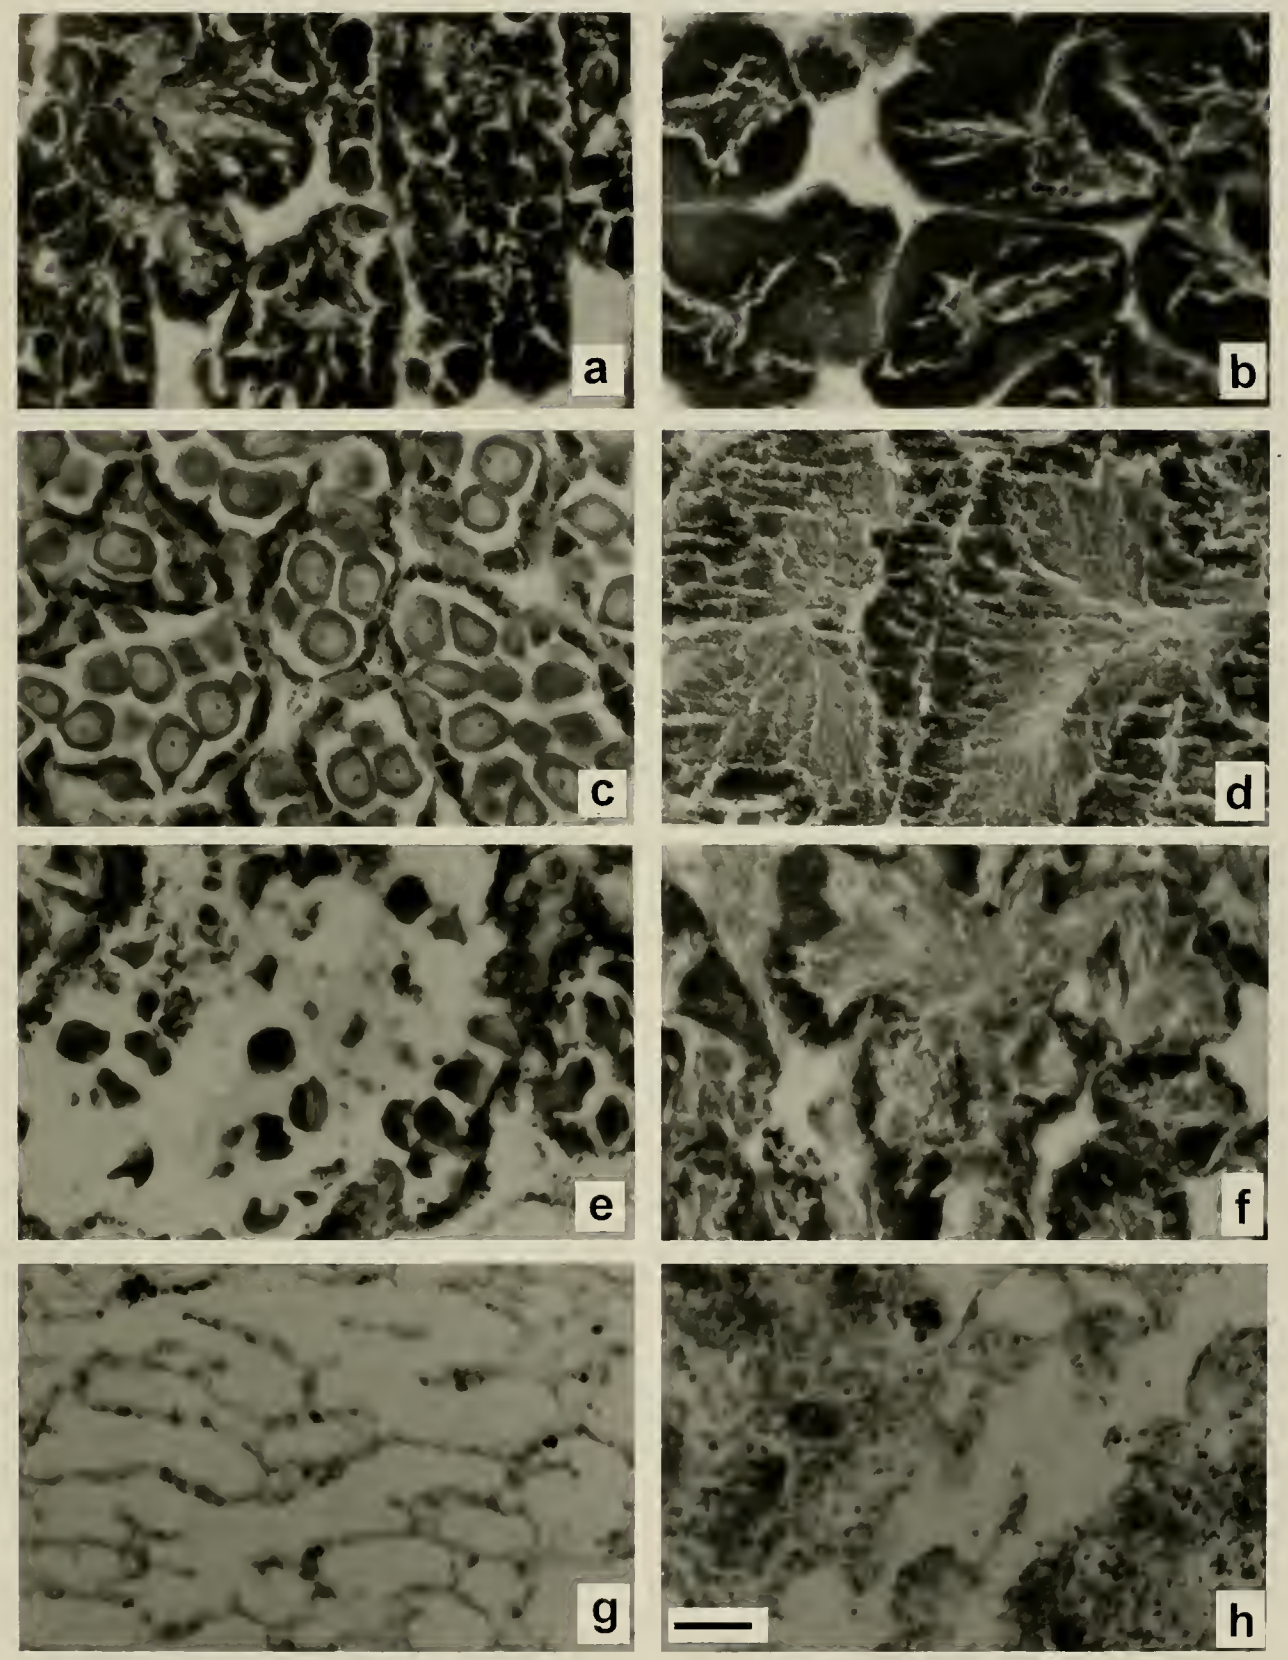

Figure 1. Photomicrographs of gonadal stages of *P. rugosa*. (a) Gonad classified as developing female; small oocytes growing attached to the follicle wall, male spent. (b) Developing male; thick layer of spermatocytes developing. (c) Mature female; large oocytes free in the lumen of follicles. (d) Mature male; large quantity of spermatozoa filling the follicles. (e) Partially spawned female; empty follicle with some residual oocytes. (f) Partially spawned male; a marked decrease in the number of spermatozoa filling the lumen. (g) Indifferent gonad; follicles with total absence of gametes. (h) Gonad spent; follicles collapsed, amebocytes phagocytizing residual gametes. Scale bar = 50 μm.

values obtained permit us to realize the correlation analysis of reproductive activity with temperature and photoperiod.

Data for photoperiod for this study were not determined directly by the authors. Data from nautical almanacs of the Secretaria de Marina of Mexico were used to define the photoperiod. The data correspond to the daily period of illumination, and an average in minutes of illumination was calculated for each month, between February 1993 and February 1994, for the latitude corresponding to Bahía Concepción.

A Spearman rank order correlation analysis was used to investigate the relationship between GI, temperature and photoperiod. Correlation analysis were carried out with the monthly values (n = 13).

RESULTS

A total of 311 specimens was collected, 33 females (10.6%), 55 males (17.7%), 65 hermaphrodites (20.9%), and 158 indifferentiated (50.8%). The range in shell length of pen shells was from 134 to 366 mm (258 mm average, 29 mm standard deviation).

In the hermaphrodite gonads, the development of both sexes was not synchronous. On the contrary, one sex was always in a more advanced stage of development (*i.e.*, the female phase was developing, whereas the male phase was spent) (Fig. 1a).

To describe the reproductive cycle, all of the organisms were considered, including the hermaphrodites. In the case of hermaphrodites, they were each considered as one individual accordingly with the more advanced developing stage. The similar range of gonadal development for small to large individuals indicated that all pen shell sampled were reproductively active. All five stages of gonadal development were observed (Fig. 1).

The reproductive cycle of *P. rugosa* from Bahía Concepción, Gulf of California, is summarized in Figure 2. Indifferent individuals were observed all year, except in June. In February 1993 and from December 1993 to February of 1994, most pen shell were indifferent staged (94.1%, 100%, 93%, and 100%, respectively). Gametogenesis commenced in March. Maturation was continuous through November. Ripe stage was present from April to November, except in September. The partially spawned stage was present in May and from July through November. Spent specimens occurred from May to September, except in June.

Monthly quantitative assessments of histological reproductive condition are illustrated in Figure 3a. From these data, it is apparent that the GI has a seasonal tendency along the year, with high values coinciding with ripe individuals and the fall of values coinciding with spawning activity. The values of GI were higher in April, June, and October and were lower from December to February. The GI values indicated that the gametogenesis started in March and continued until November, with pen shell quiescent from December to February.

Water temperature showed considerable seasonal variation (Fig. 3b) with extreme values of 31 °C in August and 19 °C in February.

The photoperiod (minutes of daily illumination) is illustrated in Figure 3c. The longest monthly average daily illumination in the study area occurred during May to July, with the highest in June (820 min). The minutes of daily illumination presented a decreased tendency during July through November. The shortest time of illumination occurred in November/December and January (640 min).

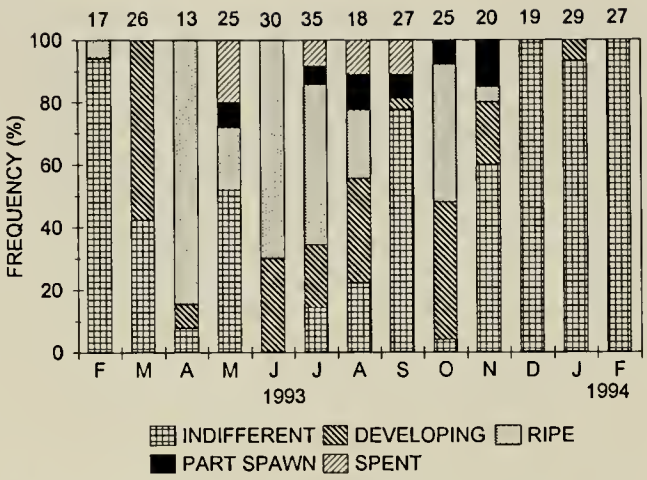

Figure 2. Reproductive cycle of *P. rugosa* from Bahía Concepción, Gulf of California, Mexico. Relative frequency of gonadal stages between February 1993 and February 1994. Observations of males and females are combined. Numbers at top indicate the sample sizes for each month.

In all cases significant correlation ($P < 0.05$) was found. The GI presented a positive correlation with temperature (n = 13; r = 0.85; P = 0.000192) and photoperiod (n = 13; r = 0.69; P = 0.008980). Temperature and photoperiod were positively correlated (n = 13; r = 0.59; P = 0.031929).

DISCUSSION

In Bahía Concepción, the rugose pen shell exhibits an annual gametogenic cycle, which commences in March with rapid prolif-

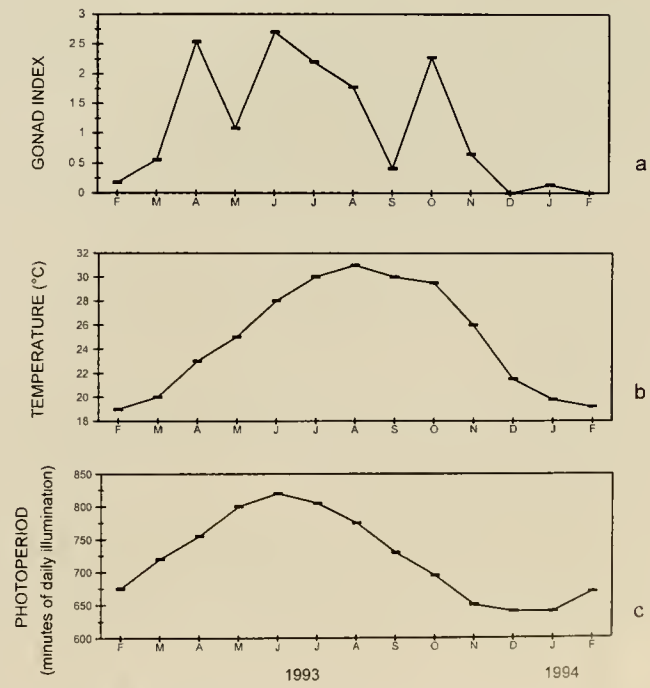

Figure 3. Monthly variation of GI (a), water temperature (b), and photoperiod (c) in Bahía Concepción, B.C.S., Mexico.

eration of gametes and ends by December. According to the histological analysis, the spawning occurs from May to November, except in June. Our results are in agreement with the reproductive cycle of *P. rugose* occurring in La Paz Bay, B.C.S., México, as described by Noguera and Gómez-Aguirre (1972), who documented that sexual maturation begins in mid-spring, with spawning occurring by late summer.

The characteristics of gametogenesis in *P. rugosa* from Bahía Concepción were similar to those described for *Spondylus leucacanthus* from Isla Danzante (Villalejo-Fuerte and García-Domínguez 1998). The gonad of *P. rugosa* has oocytes with the same degree of development, common for bivalves with a synchronic development. The histological examination additionally showed that *P. rugosa* is a hermaphrodite species; in this study 20.9% of pen shell presented this condition. Hermaphroditism is common in bivalves (Tranter 1958, García-Domínguez et al. 1996, Villalejo-Fuerte and García-Domínguez 1998).

There are two basic types of reproductive pattern exhibited by marine bivalves in the Gulf of California waters. Many bivalve species have no seasonal reproductive cycle, and their spawning activity is continuous, for example, *Megapitaria aurantiaca* (García-Domínguez et al. 1994) and *Pinctada mazatlanica* (García-Domínguez et al. 1996). Other bivalve species exhibit distinct seasonal reproductive cycles, such as *Dosinia ponderosa* (Arreola-Hernández 1997), *Chione undatella* (Baqueiro and Masso 1988), and *M. squalida* (Villalejo-Fuerte et al. 1996), which usually are related to temporal variations of environmental factors such as food availability, water temperature, and/or photoperiod.

The reproductive activity of *P. rugosa* was significantly correlated to the water temperature and photoperiod. The protracted period of reproductive activity (March to November 1993) of *P. rugosa* from Bahía Concepción coincides with the gradual increase of sea-surface temperature (from 20 °C until a maximum of 31 °C), and with increased values of photoperiod (720 min/day). The period of reproductive inactivity was clearly distinguished in winter (November 1993 to February 1994), and coincides with an abrupt decrease of 3.5 °C in the sea-surface temperature (26 °C) and with the photoperiod minimum values (640–650 min/day).

The Spearman correlation analyses indicated that the major environmental factor that directly influences the gonadal growth is the water temperature, suggesting that the production of gametes is stimulated by increases in temperature. The same has been observed for other bivalve species, such as *Spondylus leucacanthus* (Villalejo-Fuerte and García-Domínguez 1998) and *Argopecten circularis* (Villalejo-Fuerte and Ochoa-Baez 1993). However, in other bivalves from the Gulf of California, no clear relationship exists between gonadic development and water temperature (*e.g., M. aurantiaca* [García-Domínguez et al. 1994] and *P. mazatlanica* [García-Domínguez et al. 1996]). Although water temperature affects reproduction, other environmental factors may well play an integral role in determining the pattern of annual gonad activity for species in a given geographical area (Sastry 1970).

Giese and Pearse (1974) have reported photoperiod as a factor that influences spawning of invertebrates. However, it has not been widely studied in bivalves (Villalejo-Fuerte and Ochoa-Báez 1993). The temperature and photoperiod are positively correlated. But it may not be possible to separate the effects of these two factors with the data presented in this paper.

ABSTRACT Chromosome segregation in fertilized eggs of the zhikong scallop, *Chlamys farreri*, following polar body 1 (PB1) inhibition with cytochalasin B (CB) was studied. The fertilized eggs were treated with CB (0.75 mg/L) at 7–10 min postfertilization until polar body 2 (PB2) was released in control groups. The embryos were sampled every 5–10 min after fertilization and fixed in Carnoy fixative. Chromosome segregation in both control groups and treated groups were analyzed using a hematoxylin stain method.

In fertilized eggs of control groups, the 19 tetrad chromosomes went through meiosis I and II, and released PB1 and PB2, finally reaching 19 chromatids. In CB treated groups, meiosis I proceeded normally and produced two groups of dyads, 19 in each group. With the CB treatment, both of the two dyad groups were retained in the eggs and entered meiosis II. The segregation in meiosis II had four patterns: bipolar, tripolar, tetrapolar, and unsynchronized segregation. When the two groups of dyads from meiosis I united, the treated eggs entered meiosis II through tripolar (40.9%) and bipolar (11.4%) segregation patterns. Otherwise the two groups of dyads segregated separately and formed tetrapolar segregation (15.7%). Also a small proportion of treated eggs (4.0%) underwent meiosis II in an "unsynchronized segregation" pattern, which means that the two groups of dyads from meiosis I did not segregate synchronously. There were 28.0% of treated eggs that could not be classified. The four segregation patterns produced different ploidies of embryos in CB treated groups, such as triploids, tetraploids, pentaploids, and aneuploids.

KEY WORDS: Zhikong scallop, *Chlamys farreri*, chromosome segregation, triploid, tetraploid, polar body

INTRODUCTION

Triploids can be induced by blocking the first polar body (PB1) in some mollusk species, such as American oyster, *Crassostrea virginica* (Stanley et al. 1981), Pacific oyster, *Crassostrea gigas (Thunberg)* (Quillet and Panelay 1986), Pacific abalone, *Haliotis discus hannai* (Arai et al. 1986), pearl oyster, *Pinctada martensii* (Jiang et al. 1987), and blue mussel, *Mytilus edulis* (Yamamoto and Sugawara 1988). Tetraploids were also reported among triploids in American oyster (Stanley et al. 1981) and in other mollusk species (Arai et al. 1986, Yamamoto and Sugawara 1988). Stephens and Downing (1988) reported that 91% tetraploid at 24-h postfertilization (PF) was produced by inhibiting PB1 in fertilized eggs from the Pacific oyster. In similar work, Guo et al. (1992a) reported that many aneuploids embryos (57.6%) were also produced. All of these results indicate that PB1 inhibition results in complicated chromosome segregation. Observation of chromosome segregation in the Pacific oyster explained the mechanism for formation of different ploidies when PB1 was blocked (Guo et al. 1992b). Three different types of segregation, including "tripolar segregation," "united bipolar segregation," and "separated bipolar segregation" were evident. Later, the chromosome segregation in triploid Pacific oysters was also studied when eggs from triploids were fertilized with diploid sperm and PB1 was blocked with CB (Que et al. 1997). The observation showed that there were also three types of segregation patterns, confirming the mechanism by which viable tetraploid Pacific oysters can be successfully induced through blocking PB1 in fertilized eggs from triploids (Guo and Allen 1994).

In the zhikong scallop, *Chlamys farreri*, blocking PB1 in fertilized eggs from normal diploids can result in triploid, tetraploid, pentaploid, and aneuploid embryos. We have also found that both triploids and tetraploids can survive to 2–3 mm juvenile stage (unpublished). In this paper, the behavior of chromosome segregation was observed in fertilized eggs from normal diploids when PB1 was blocked with CB, offering an explanation for the formation of embryos with different ploidies.

MATERIALS AND METHODS

Gametes

Parent scallops were from Rizhao and Qingdao, Shandong, China. The scallops were conditioned indoors to accelerate gonad maturity. Gametes were obtained through natural spawning. Eggs were collected with a 25-μ screen and resuspended into 2 ~ 3 L seawater at 20 °C, ready for fertilization. Sperm were prepared by screening sperm suspension through a 25-μ nylon screen. For fertilization, sperm were added to the egg suspension at a final density of 5–7 sperm per egg. Fertilization, treatment, and embryo culture were all conducted at 20 °C.

Treatment and Sampling

PB1 in fertilized eggs was blocked with 0.75 μg/mL CB dissolved in dimethyl sulfoxide (DMSO-final concentration 0.1%). CB treatment began at 7–10 min PF and ended when the second polar body (PB2) in control groups was observed under microscope. Fertilized eggs in both control groups and CB-treated groups were sampled every 5–10 min during development until 75 min PF. Samples were directly fixed in Carnoy fixative (methanol: acetic acid = 3:1), which was changed twice, and the samples were then stored at 4 °C before analysis. The experiment was repeated four times using different parent scallops.

Chromosome Observation

Slides for observing chromosomes were made by a modified squashing method. The staining solution was made by dissolving 0.5% hematoxylin in 45% acetic acid, with ammonium iron sulfate

dodecahydtate as a mordant (about 0.5%). Embryo samples were dropped and spread on clean slides. Excessive fixative was allowed to run off the slides, and then drops of staining solution were added onto the samples just before the fixative evaporated. A clean cover glass was placed gently on the samples. Before squashing on filter paper, slides were warmed slightly by passing them across an alcohol burner. Then, the cover glass was sealed on all four sides. Alternatively, the whole cover glass was sealed with neutral balsam after removal by icing the slides.

Slides were examined with a Nikon compound microscope. Photographs were taken using LUCKY black and white film (ASA 100 and 400).

RESULTS

Initially, normal diploid eggs were observed in prophase of meiosis I (Fig. 1a). Zhikong scallop has a diploid number of 38 chromosomes (Wang et al. 1990). Nineteen tetrads were observed in the unfertilized eggs.

In control groups, the 19 tetrads began to segregate at about 9–10 min PF, then the tetrads in the majority of fertilized eggs segregated into 38 dyads, and then divided into two groups, 19 in each group (Fig. 1b). Later, one group of dyads condensed and released as PB1 (Fig. 1c). The remaining 19 dyads continued meiosis II and segregated into two groups of chromatids (Fig. 1d). One of the groups of chromatids was released as PB2 in most fertilized eggs at 40–43 min PF. Normally, the two polar bodies were positioned next to each other (Fig. 1e). As for the chromatids from sperm, at first, they could only be observed as dark-stained material. Only during mitosis 1, did the chromatids from egg and sperm unite, yielding 38 chromosomes.

In CB-treated groups, chromosome segregation was complicated. After fertilization, the 19 tetrads segregated into 38 dyads (Fig. 1g). Under the microscope, no PB1 was released in the majority of treated, fertilized eggs during CB treatment. Thus, 38 dyads in fertilized eggs entered meiosis II, and chromosome segregation differed greatly from that in control groups. Four patterns of segregation were observed: bipolar, tripolar, tetrapolar, and unsynchronized. Some segregations could not be classified. When the 19 dyads from PB1 united with the other 19 dyads, the chromosome segregation in meiosis II proceeded with bipolar or tripolar segregation.

Bipolar Segregation

The 19 dyads from PB1 united with the remained 19 dyads, and went through meiosis II together (Fig. 1h). All 38 dyads segregated in a bipolar pattern just like normal meiosis II, and divided into two groups of sister chromatids, 38 in each group (Fig. 1i). One of the two groups of chromatids was released as PB2 after CB treatment. This pattern of chromosome segregation could result in triploids.

Tripolar Segregation

The 38 united dyads divided into three groups, apparently at random (Fig. 1j), and the dyads in each group segregated in two directions. Finally, the chromatids migrating in one direction united with the chromatids from its neighboring group at a pole, forming three groups of chromatids (Fig. 1k). The number of chromatids in the three groups varied considerably, apparently depending upon random distribution of dyads before meiosis II. Rarely, one of the three groups had exactly 19 chromatids. In this pattern of chromosome segregation, the three groups of chromatids had probability of being released as PB2 after CB treatment.

Sometimes the 19 dyads from the unreleased PB1 fail to unite with the remaining 19 dyads in the fertilized eggs (Fig. 1l). They entered meiosis II independently, resulting in two patterns of chromosome segregation: tetrapolar and unsynchronized segregations.

Tetrapolar

In both dyads groups, the chromosomes segregated in a normal bipolar pattern. The final result was that four groups of chromatids formed, 19 chromotids in each group (Fig. 1m).

Unsynchronized Segregation

The unreleased dyads and the remaining dyads in the fertilized egg went through meiosis II asynchronously. Sometimes one group of dyads did not go through meiosis II, but remained unchanged, and another group of dyads went through meiosis II and underwent bipolar segregation to anaphase (Fig. 1n).

Unclassified

In addition to the above segregation patterns, there were also other patterns that could not be classified. In fertilized eggs with 38 united dyads, only some began meiosis II segregation; whereas, some were left as dyads. In some treated fertilized eggs, the 38 dyads went through meiosis II, but the 76 chromatids distributed themselves randomly. No segregation poles were observed (Fig. 1o).

The frequencies of the four segregation patterns were calculated from embryos where PB1 had been blocked (Table 1). On average, the majority of treated eggs went through meiosis II as tripolar segregations (40.9%), 11.4% were bipolar, and 15.7% were tetrapolar. Only a small proportion of treated eggs (4.0%) went through unsynchronized segregation. Finally, 28.0% of segregations in treated eggs could not be classified.

DISCUSSION

We made slides for observing chromosome segregation by a modified squashing method using a hematoxylin stain. For fertilized eggs and embryos from the zhikong scallop, this procedure was quite useful. In fertilized eggs of the Pacific oyster, orcein dissolved in 60% acetic acid employed chromosome observations (Guo et al. 1992a, Que et al. 1997). In the zhikong scallop, we have tried orcein staining, but it produced poor contrast. Hematoxylin is a typical chromosome stain (Sharma and Sharma 1980). Normally hematoxylin solution must be made in advance to ripen for a few weeks. In this experiment, the stain solution was modified as 0.5% dissolved in 45% acetic acid with ammonium iron sulfate as mordant and could be used instantly. In addition, this method produced satisfactory results for observing chromosomes in the fertilized eggs and embryos from the jinjiang oyster, *Crassostrea ariakensis* (unpublished). We suggest this new staining method for chromosome observations in bivalve mollusk.

Chromosome Segregation

Unfertilized eggs of normal diploid zhikong scallops are arrested at late prophase of meiosis I. Only after fertilization, did the eggs continue meiosis I and II, releasing PB1 and PB2. In the end, 19 maternal chomatids remained in the fertilized eggs. This pattern of chromosome segregation is common among bivalve mollusks (Longo and Anderson 1969).

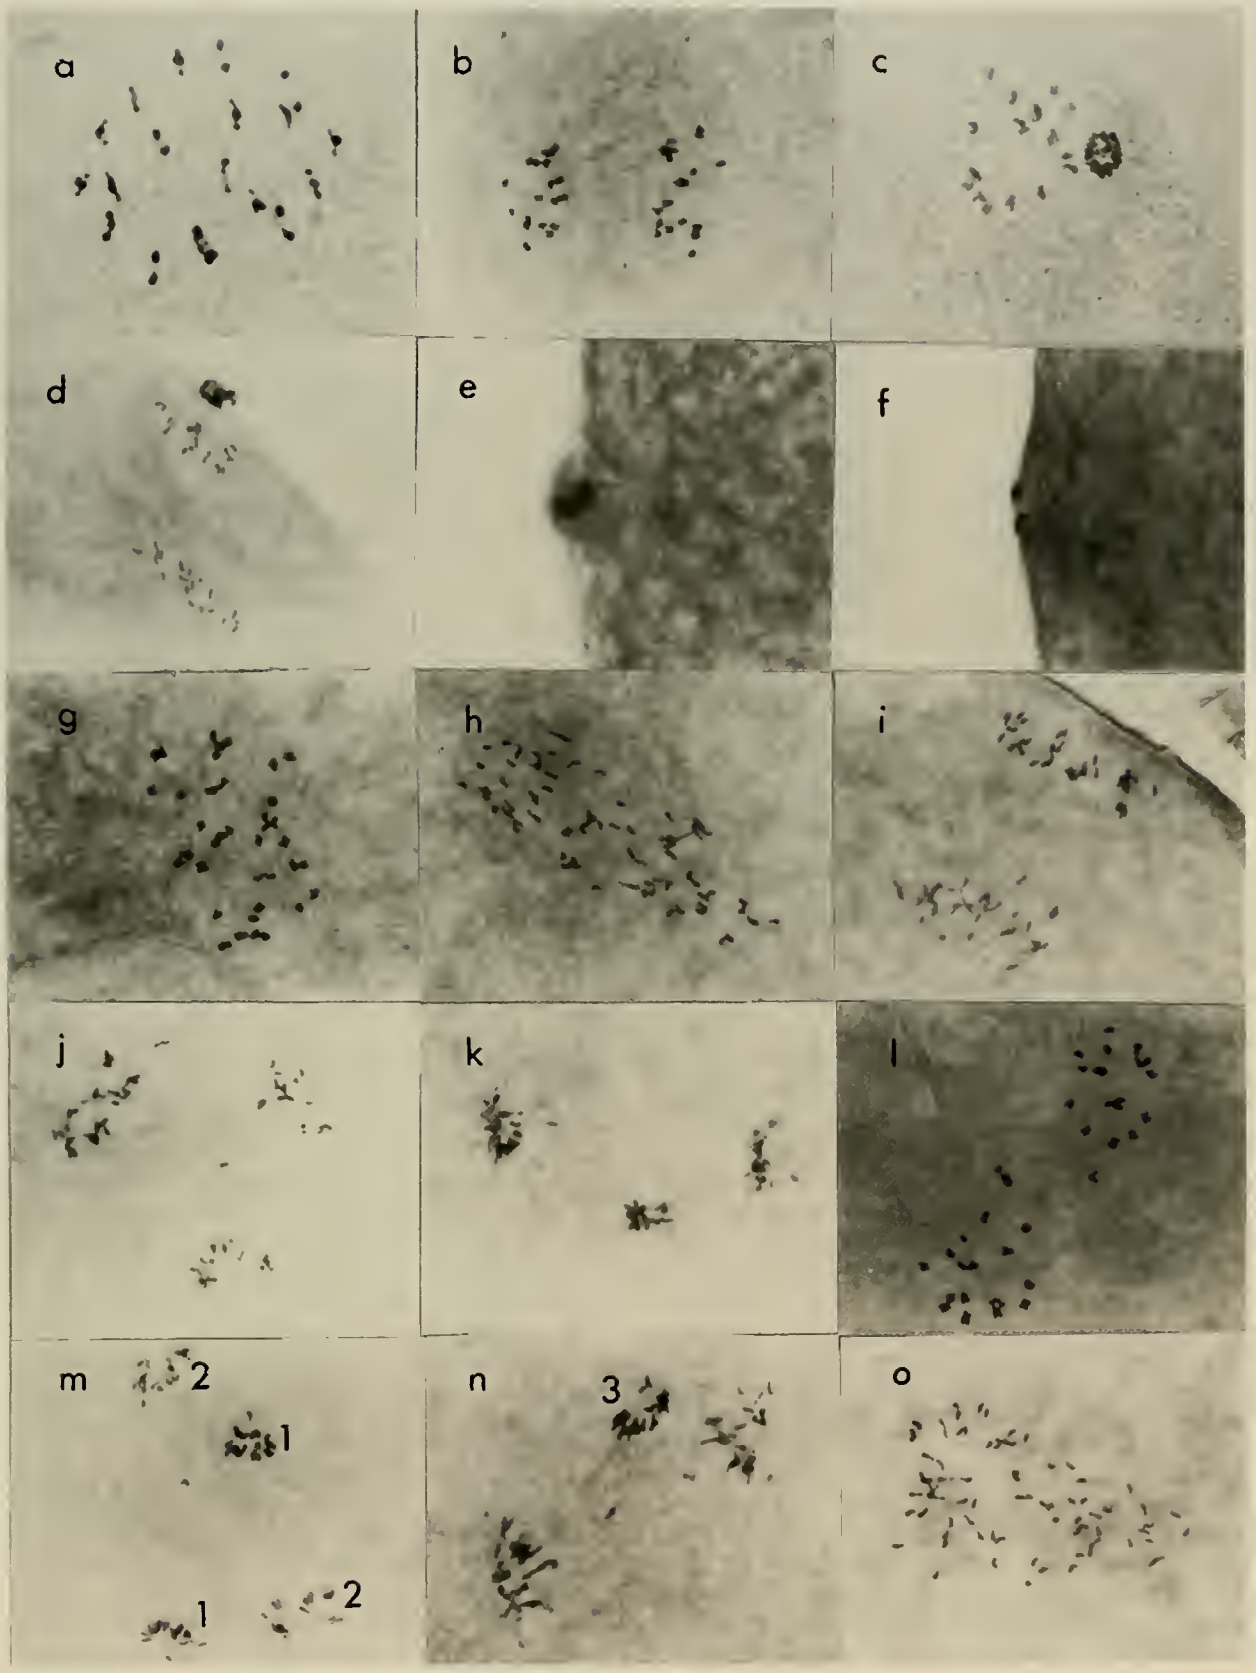

Figure 1. Segregation patterns observed in fertilized eggs from diploid zhikong scallop, *Chlamys farreri*, following normal fertilization (a–e) and PB1 blocking with Cytochalasin B (f–o). a–e: meiosis in normal fertilized eggs; f: two polar bodies positioned side-by-side in fertilized eggs following PB1 blocking with CB; g: the united 38 dyads. h–i: bipolar segregation pattern; j–k: tripolar segregation pattern; l–m: tetrapolar segregation pattern. 1 and 2 indicated two separate poles; n: unsynchronized segregation pattern. 3 indicated dyad groups; o: unclassified segregation pattern.

TABLE 1.

Chromosome segregation patterns (%) in fertilized eggs when PB1 was blocked with CB in zhikong scallop *Chlamys farreri*.

Replicate (Number)	Chromosome Segregation Patterns					
	n	Bipolar	Tripolar	Tetrapolar	Unsynchronized	Unclassified
1	109	11.0	45.9	17.4	1.8	23.9
2	162	7.4	46.9	17.3	4.3	24.1
3	106	13.2	46.2	11.4	2.8	26.4
4	85	14.1	24.7	16.5	7.1	37.6
Average		11.4	40.9	15.7	4.0	28.0

In CB-treated groups, chromosomes in fertilized eggs, following PB1 blocking, segregated in four patterns: bipolar (11.4%), tripolar (40.9%), tetrapolar (15.7%), and unsynchronized (4.0%). Bipolar, tripolar, and tetrapolar segregation patterns were similar to those reported in diploid (Guo et al. 1992b) and triploid Pacific oysters (Que et al. 1997) when PB1 was blocked.

In addition, in the zhikong scallop a small proportion of treated eggs (4.0%) went through meiosis II asynchronously. Blocked dyads from PB1 failed to unite and segregated asynchronously from the remaining dyads. Sometimes the remaining dyads went to anaphase of meiosis II and divided into two groups of chromatids, while the dyads from blocked PB1 remained paired and skipped meiosis II, leaving three chromatin groups. In eggs of triploid Pacific oysters, asynchronous segregation was also observed when crossed with a normal sperm of diploid followed by PB1 inhibition by CB (Que et al. 1997). In the Japanese pearl oyster, *Pinctada fucata martensii*, Komaru et al. (1990) reported that three groups (20.6%) and four groups (17.6%) of maternal chromatin were produced by blocking PB1. The observation of three groups of chromatin might be explained in two ways: asynchronous segregation or tripolar chromosome segregation, both resulting in three chromatin groups. The percentage of fertilized eggs with three groups of maternal chromatin (20.6%) as observed by Komaru was much lower than our observations of tripolar segregation (40.9%) and asynchronous segregation (4.0%) in the zhikong scallop. This is possibly caused by differences in chromosome segregation between the different species or because the conditions of CB treatment were different. In diploid Pacific oysters, chromosome segregation following PB1 inhibition was observed to pass through meiosis II synchronously (Guo et al. 1992b).

In addition to the described four segregation patterns, there was a large proportion of chromosome segregations (28.0%) that could not be classified, such as 76 chromatids scattered randomly. Unclassified segregation patterns have also been observed in both diploid and triploid Pacific oysters (Guo et al. 1992b, Que et al. 1997). Considering the results of this experiment and those in diploid and triploid Pacific oysters and pearl oysters, we suggest that tripolar, tetrapolar, bipolar, and unsynchronized segregation patterns are the normal ways for fertilized eggs to go through meiosis II after PB1 blocking.

Observations of chromosome segregation using the squashing method provide an incomplete picture of cytological events, because compression of the eggs transforms the three dimensionality of the meiotic plates into a plane, thus rearranging the position of chromosomes. This method also fails to display centrosomes and spindles that play an important role in meiosis. Observing centrosomes and spindles might provide a clearer picture of how chromosomes segregated. Especially for the centrosome, its number and replication are critical factors in the chromosome segregation. Normally the centrosome from sperm does not participate in meiosis (Sluder et al. 1993), and the centrosome from maternal replicates two times with each meiotic stage, resulting in the normal bipolar segregation. In this experiment, we hypothesize that centrosome number is the primary factor controlling patterns of chromosome segregation. With PB1 blocked in eggs, centrosome number could change profoundly, affecting chromosome segregation in meiosis II. Centrosome numbers could range from 2–4, depending upon whether centrosomes replicated, and could result in bipolar, tripolar, or tetrapolar chromosome segregation patterns. This supposition must be tested by visualization of the centrosomes, spindles, or both.

Ploidy Consequences

In the zhikong scallop, diploid, triploid, tetraploid, pentaploid, and aneuploid 2–4 cell stage embryos were all produced when PB1 was blocked in fertilized eggs. Both triploid and tetraploid zhikong scallops survived to juvenile stage (21.3% triploid and 1.9% tetraploid in one group, unpublished). The various ploidy consequences of PB1 blocking relate to the different chromosome patterns, as observed in this study.

First, bipolar segregation patterns formed two groups of 38 chromatids. Either of the two chromatids group could be released as PB2, leaving 38 chromatids. No matter which group was released, triploids would be produced by bipolar segregation with 19 chromosomes contributed by the sperm.

For tetrapolar segregation patterns, four separated chromatids groups were formed after meiosis II, 19 chromatids in each group. The ploidy consequences would depend upon how many chromatid groups would be released with PB2. Release of one group would produce tetraploids; whereas, release of two groups would produce triploids and release of three would produce diploids. After CB was washed off, embryo development showed that some fertilized eggs in the treated groups released one PB, and some fertilized eggs released two PBs positioned side-by-side (Fig. 1f) or separated from each other on the egg. Rarely were these two polar bodies positioned next to each other, as in Figure 1e. It was impossible by our methods to observe total number of chromatids in released PBs. This problem might be resolved by using special staining methods to label chromatids individually, such as *in situ* fluorescent hybridization.

The ploidy consequences of embryos after tripolar segregation were the most complicated because of random allocation of chromatids at three poles and the random release of PB2. The metaphase and anaphase period in meiosis II were very short, so it was not practical to count numbers of chromatids at the three poles in most fertilized eggs. By counting the chromosome of 2–4 cell embryos, we could infer that chromosome number varied highly.

In tripolar segregations, tetraploids would be produced only when one pole had exactly 19 chromatids, and the chromatids at this pole were released as PB2. If the 19 chromatids at one pole remained in the eggs, and the chromatids at the other two poles were released as PB2, diploids would be produced. Otherwise, aneuploids resulted. The majority of fertilized eggs proceeded by tripolar segregation (40.9%), explaining why about 23.3% of 2–4 cell stage embryos were aneuploid (unpublished). In most aneuploids, chromosome numbers were distributed mainly into three groups: 42–48, 62–69, or 83–89, most likely the result of random allocation of chromatin from the three poles.

Unsynchronized segregation resulted in three groups of chromatin, two with 19 chromatids in each and the other with 19 dyads from blocked PB1. Diploids, triploids, and tetraploids could possibly be produced, depending upon which group was released as PB2. Supposing one group of 19 chromatids was released as PB2, tetraploids would be produced. If 19 dyads were released as PB2, triploids would be produced. If two groups of chromatin were released as PB2, triploids or diploids would be produced.

Pentaploids were also observed at the 2–4 cell embryo stage (unpublished). The formation of pentaploidy was probably caused by the failure of PB2 to be released in fertilized eggs after PB1 was blocked with CB. Thus, the 76 chromatids from maternal chromotids plus the 19 chromatids from sperm formed pentaploids.

Clearly, differences in chromosome segregation resulted in different ploidy consequences and agree with the proposed mechanism to form different ploidies in diploid Pacific oyster when PB1 was blocked (Guo et al. 1992b). PB1 blocking is also an effective way to induce triploids and tetraploids. Both triploid and tetraploid embryos have been produced through blocking PB1 in fertilized eggs from normal diploid, such as in Pacific oyster (Guo et al. 1992a), American oyster (Stanley et al. 1981), Pacific abalone (Arai et al. 1986) and blue mussel (Yamamoto and Sugawara 1988).

In summary, the inhibition of PB1 in fertilized eggs of zhikong scallop with CB resulted in complicated chromosome segregation patterns, including bipolar, tripolar, tetrapolar, unsynchronized, and unclassified segregations, producing diploid, triploid, tetraploid, pentaploidy, and aneuploid embryos. This study provided cytological evidence about possible formation of different ploidies and valuable information on polyploid induction.

ABSTRACT The reproductive cycle of the catarina scallop *Argopecten ventricosus* and its relation to temperature, salinity, and quantity of food was studied in the Rada del Puerto de Pichilingue, B.C.S. Mexico, from April 1995 to March 1996. Organisms were obtained from a hatchery and grown on the bottom. Ripe organisms occurred throughout the year showing the lack of seasonality in its reproduction. No consistent relation between reproductive cycle and environmental factors or food was evident. The muscle yield index showed a significant positive correlation with temperature, but it had no correlation with gonadosomatic index. The relation between the muscle yield index and seston with the reproductive cycle suggested the transference of energy from the muscle to the gonad and directly from the seston ingested. This relation suggested that *A. ventricosus* is a conservative and opportunistic species depending on the available food. Histochemical analysis revealed the transference of carbohydrates from the intestinal loop to the gonad and therefore to the oocytes.

KEY WORDS: *Argopecten*, reproductive cycle, bivalves, histochemistry, seston, food index

INTRODUCTION

The scallop *Argopecten ventricosus* (Sowerby 1842) is distributed from Isla Cedros and the Gulf of California to Peru (Keen 1971). *A. ventricosus* supports an important fishery in northwest Mexico, especially in Baja California Sur (Chávez-Villalba and Cáceres-Martínez 1992). It is an important resource because of the high commercial value of its adductor muscle (Villalejo-Fuerte and Ochoa-Báez 1993).

The necessity of measures for the regulation of the fishery has prompted several studies about reproduction of the catarina scallop in Baja California Sur (Baqueiro et al. 1981, Cáceres-Martínez et al. 1990, Villalejo-Fuerte and Ochoa-Báez 1993, Félix-Pico et al. 1995).

The reproductive cycles of scallops are influenced by changes in environmental variables, such as temperature and food (MacDonald and Thompson 1985, Barber and Blake 1991), and by genetic characteristics (Barber and Blake 1991). Gametogenesis needs a lot of energy (Sastry 1979). This energy is obtained directly from the seston or from storage organs or tissues, like the digestive gland, mantle, and adductor muscle (Ansell 1974, Gabbott 1975, Barber and Blake 1983).

The seston includes live plankton, organic detritus, and inorganic particles (Navarro and Thompson 1995). The quantity and quality of seston varies in response to physical and biological factors such as tides, storms, wind, bacteria, fungi, and primary consumers (Berg and Newell 1986, Mann 1988).

The objective of the study is to examine the reproductive cycle of *A. ventricosus* in relation to its condition, histochemical composition of somatic and reproductive tissues, temperature, salinity, and quantity of available food.

MATERIALS AND METHODS

Between April 1995 and March 1996, 30 specimens of *A. ventricosus* (shell height mean ± SD = 5.25 ± 0.02 cm) were collected randomly per month by diving between 3- and 4-m depth from a population grown in the Rada del Puerto de Pichilingue, B.C.S., Mexico (24°16′N; 110°19′W). These organisms were initially produced in September 1994 at our hatchery at Universidad Autónoma de Baja California Sur and seeded on the bottom in February 1995. The surface water temperature and salinity were recorded at the time of sampling. Total soft body, adductor muscle, and gonad wet weights were recorded for each specimen.

Reproductive Cycle

The scallops were fixed in 10% formalin. Tissue sections were taken through the middle of the gonad, dehydrated in alcohol, and embedded in paraffin wax. Sections (5 μm) were placed on slides and stained with hematoxylin-eosin (Humason 1979). Gametogenesis (either spermatogenesis or oogenesis) of *A. ventricosus* was divided into five stages (undifferentiated, developing, ripe, spawning, and spent) on the basis of the developmental stages defined by Villalejo-Fuerte and Ochoa-Báez (1993) for the same species and our own observations.

Undifferentiated Stage

Abundant connective tissue, without germ cells or residual gametes. It was not possible to distinguish the sex.

Developing Stage

In the female, this stage is characterized by the presence of variable quantities of developing oocytes attached to the follicle

wall. Some detached ripe oocytes occurred in the lumen of the follicle. In the male, this stage had variable quantities of germinal cells, spermatocytes, spermatids, and ripe spermatozoa. Interfollicular connective tissue decreases and follicles increase in area as the result of the accumulation of ripe gametes.

Ripe Stage

In the female, there were abundant, ripe polygonal-shaped oocytes free within the follicles. Yolk droplets were observed in the oocyte cytoplasm. Some developing oocytes remained attached to the follicle wall by a slender stalk. In the male, this stage was characterized by follicles filled with ripe spermatozoa arranged in characteristic radial bands with tails pointing toward the center of the lumen. Almost all the connective tissue has been completely replaced by follicles forming the gonadic tissue, which is occupied by gametes.

Spawning Stage

The walls of follicles become broken. Variable quantities of unspawned oocytes and spermatozoa were observed into the follicles. Free spaces inside the follicles were abundant. Some follicles are completely devoid of gametes.

Spent Stage

The follicles were empty, with the exception of some residual oocytes and spermatozoa. Connective tissue begins increasing. The broken follicles are invaded by phagocytes. The relative frequencies of the stages of gonadal development throughout the year were obtained. This enabled the description of the reproductive cycle.

Gonadosomatic Index (GSI)

This index in wet weight was calculated according to Sastry and Blake (1971).

$$GSI = \frac{GW}{TSBW} * 100$$

Where GSI is the gonadosomatic index, GW is the gonad weight in grams, and TSBW is the total soft body weight in grams.

Muscle Yield Index (MYI)

The muscle yield index was calculated as an indicator of the condition of the scallops (Cáceres-Martínez et al. 1990).

$$MYI = \frac{MW}{TSBW} * 100$$

Where MYI is the muscle yield index, MW is the weight of muscle in grams, and TSBW is the total weight of the soft body in grams.

Histochemical Analysis

Four scallops corresponding to each stage of gonadal development (twenty in total) were collected in September 1995 for histochemical analysis (qualitative analysis) of gonad, mantle, and muscle to determine carbohydrate and lipid content. Unfortunately, we did not take samples since April 1995 to get an annual cycle. Tissue sections were embedded in paraffin wax and O.C.T. compound (an embedding medium for frozen tissue specimens). Sections 5-μm thick from paraffin wax and sections 16-μm thick from O.C.T. were placed on slides. The oil red technique (Spannhof 1966, Martoja and Person 1970) was used on frozen cuts to determine unsaturated lipids. Periodic acid of the Schiff-Malt technique was used to determine glycogen (Martoja and Person 1970, Sheehan and Hrapchak 1973, Humason 1979), and the blue alzian technique was used to detect acid mucopolysaccharides (Spanhoff 1966, Martoja and Person 1970).

Seston Analysis

During the study period, every 15 days, 12-L of unfiltered seawater samples of the scallop-sampling area were collected in clean plastic containers and transported to the laboratory. The seawater samples were collected at 3.5-m depth, close (about 15 cm) to the sandy bottom on which the scallops grew. The water was screened through a 180-μm Nitex mesh to eliminate large zooplankton and debris before analysis.

For dry weight and chemical analysis, 2-L of seawater for each filter (six filters in total every 15 days) were immediately filtered under gentle vacuum through washed, precombusted, preweighed Whatman GF/C filters, 4.7-cm diameter. Three filters for chemical analysis were stored at −40 °C until the analysis was done. Three filters for dry weight were dried in an oven at 80 °C for 24 h. Then they were weighed and combusted at 475 °C for 4 h. Finally, filters were reweighed after cooling in a desiccator. The particulate organic matter (organic seston) was obtained by difference of both weights.

For chemical analysis, two filters per month (one filter per sampling) with 2-mL of distilled water were ground at 5 °C in an ice bath. A 400-μL aliquot was used for lipid determination using the Bligh and Dyer (1959) method. Carbohydrates were analyzed in a 300-μL sample by the method of Dubois et al. (1956), modified by Malara and Charra (1972a). Proteins were analyzed in a 300-μL aliquot by the method of Lowry et al. (1951), modified by Malara and Charra (1972b). Results of chemical analysis were standardized for volume of seawater filtered.

Total Seston (TS)

The TS was obtained as the sum of inorganic seston and organic seston (dry weight).

Inorganic Seston/Organic Seston Ratio (IS/OS ratio)

This ratio was obtained to relate (monthly) inorganic seston to organic seston.

Food Index (FI)

An evaluation of the nutritional value of the seston throughout the annual cycle in the Rada del Puerto de Pichilingue was done using the 3 major biochemical components of the seston (lipid, carbohydrate, and protein). Thus food quantity was defined as the sum of these components and a food index was calculated according to Widdows et al. (1979) as the percentage of food material contained in the total seston.

$$FI = \frac{F}{TS} * 100$$

Where FI is the food index, F is the food material (mg/L), and TS is the total seston (mg/L).

RESULTS

Reproductive Cycle

The scallop *A. ventricosus* is a functional hermaphrodite. In the female and male follicles, the gametes were in the same developmental stage. The gonad showed well-differentiated male and female areas. Figure 1 summarizes the reproductive cycle of *A. ventricosus*. The presence of ripe gonads throughout the year indicated a prolonged reproductive period with a lack of a clear seasonal pattern. Despite this, there was a major resting period in June and September 1995 where the undifferentiated stage reached a maximum (91.3 and 46.15%, respectively). The spawning stage was observed in 9 of the twelve months sampled but reached the maximum value in August 1995 (50%).

Environmental Parameters

Temperature and salinity fluctuated relatively little (Fig. 2a). The maximum water temperature was in September 1995 (29.5 °C), and the minimum (20.5 °C) in January 1996. The maximum salinity was in January, February, and March (37 ‰), and the minimum in August and September 1995 (34 ‰).

Gonadosomatic Index

The GSI supported the results obtained in the histological analysis (Fig. 2b). The values were at a minimum in April, May, June, September, January, and increased drastically from January (4.08%) to February (7.79%) and March (8.75%).

Muscle Yield Index

The MYI was at a maximum in June and September 1995 (45.8 and 46.9%, respectively) and was at a minimum in April 1995 (33.7%) and from December 1995 to March 1996 (Fig. 2c). The MYI showed a significant positive correlation with temperature ($r = 0.797$; $P = 0.001$; $n = 12$), and a significant negative correlation with salinity ($r = -0.788$; $P = 0.002$; $n = 12$). With the GSI, there was no significant correlation ($r = -0.405$; $P = 0.190$; $n = 12$).

Histochemical Analysis

The results of the histochemical analysis of gonad, adductor muscle, and mantle are in Table 1. Positive results were found for glycogen in the female area of the gonad (developing and ripe oocytes) and in muscle fibers. Unsaturated lipids were found in the female area of the gonad (developing and ripe oocytes). Acid mucopolysaccharides were found in the interfollicular connective tissue of developing stage gonads (male and female areas), epithelium and food content of intestinal loop, and in the epithelium and connective tissue of mantle.

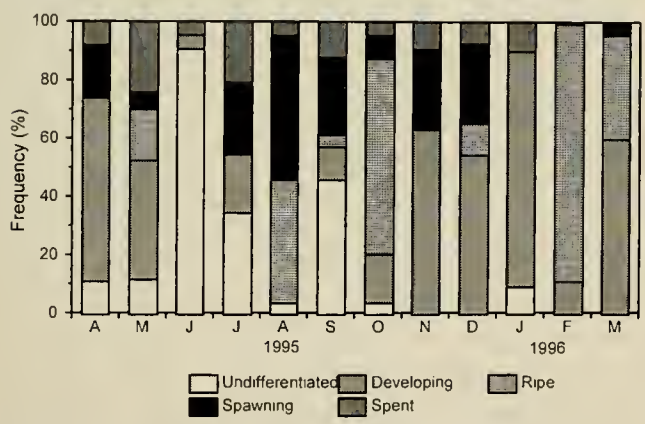

Figure 1. Reproductive stages of *Argopecten ventricosus* in the Rada del Puerto de Pichilingue, B.C.S., Mexico (n = 30).

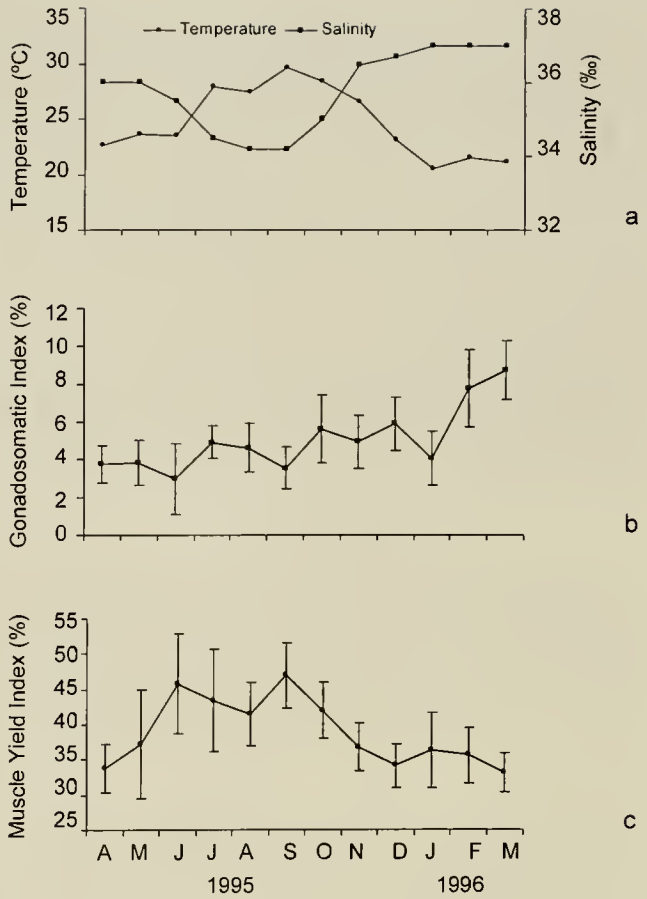

Figure 2. Water temperature and salinity in the Rada del Puerto de Pichilingue, B.C.S., Mexico (a) and gonadosomatic (b) and muscle yield index (c) of *Argopecten ventricosus*. (Error bars = SD).

Total Seston, Inorganic Seston, and Organic Seston

Sediment resuspension was caused mainly as a consequence of tidal currents and wind. In this area, maximum values of TS and IS were found in April, July, December, and January. Higher values of OS were found in April, December, and January (Fig. 3a).

Inorganic Seston/Organic Seston Ratio

The IS/OS ratio had no clear relation with the reproductive cycle (Fig. 3a). However, it showed a significant positive correlation with salinity ($r = 0.676$; $P = 0.015$; $n = 12$).

Food index

The FI expresses the quality of the diet available to a filter-feeding organism. This FI showed maximum values in July, September, and November 1995 (4.99, 5.03, and 4.97%, respectively) and minimum values in April-May 1995 (2.79 and 2.92%, respectively) and February 1996 (2.78%) (Fig. 3b). It did not show a clear relation with the reproductive cycle.

TABLE 1.

Histochemical tests performed on gonad, muscle, and mantle of *Argopecten ventricosus*.

Substance Tested	Technique	Control	Gonad	Muscle	Mantle
Glycogen	Pas-Malt	Rat liver	– oo ++ ro ++ do	++	–
Unsaturated lipids	Oil Red	None	– oo ++ ro ++ do	–	–
Acid mucopolysaccharides	Alzian Blue	None	++ ifd + ifr	–	+ mec

Abbreviations: –, not detected; +, positive reaction; ++, strong positive reaction; do, developing oocytes; ifd, interfollicular connective tissue of developing stage gonads (male and female area), epithelium and food content of intestinal loop; ifr, interfollicular connective tissue of ripe stage gonads; mec, mantle epithelium and connective tissue; oo, oogonias; ro, ripe oocytes.

DISCUSSION

The cytological characteristics of the gonad of *A. ventricosus* in the Rada del Puerto de Pichilingue, B.C.S. were similar to those described by Villalejo-Fuerte and Ochoa-Báez (1993) for the same species in Bahía Concepción, B.C.S., and for other pectinids, like *Patinopecten yessoensis* (Motavkine and Varaksine 1983) and *Placopecten magellanicus* (Beninger 1987). Male and female follicles developed simultaneously and the gametes were spawned at about the same time.

The gonads of *A. ventricosus* contained gametes in different stages of development in all the months during the annual cycle, although in lesser amount in June when the majority of the specimens were in the undifferentiated stage. Ripe organisms were present throughout the year, which suggests that this species reproduces throughout the year. Similarly, the presence of ripe organisms of *A. ventricosus* all year has been reported in other locations of Baja California Sur (Baqueiro et al. 1981, Félix-Pico et al. 1995).

Although the temperature is an important environmental factor in the regulation of bivalve reproduction (Sastry 1979), in this work, neither temperature nor salinity showed a clear relation with the reproductive cycle of *A. ventricosus* in the Rada del Puerto de Pichilingue because partly spawning scallops appear throughout the annual cycle. Maximum and minimum water temperatures coincided with the spawning (histologicaly detected) of August-September and December, as did the minimum and maximum values of salinity. The above suggests that the changes in temperature and salinity may be responsible for triggering spawning, but did not affect directly the gonadal maturation process.

In this work, the MYI did not show a significant negative correlation with GSI, but reproductive activity was present year around. An explanation of this unclear relation of the MYI with the reproductive activity is that in the Rada del Puerto de Pichilingue this species uses the available food in the environment more than muscle reserves for the gonadal maturation when the food is abundant, and they use the muscle reserves when the food abundance is poor. A transference of energy from the muscle to the gonad in *A. ventricosus* had been suggested by Cáceres-Martínez et al. (1990) and Villalejo-Fuerte and Ceballos-Vázquez (1996).

Bayne (1976) divided the bivalves into two groups based on their gametogenic pattern: 1) "conservative" species where gametogenesis occurs from energy stored in the tissue, and 2) "opportunistic" species where gametogenesis occurs when there was abundant phytoplankton. In this case, *A. ventricosus* would be named both opportunistic and conservative depending on the available food.

The MYI had a positive correlation with temperature. This may be the environmental variable that influences the transference of stored reserves from the adductor muscle to the gonad of *A. ventricosus*, as happens in *A. irradians* (Sastry and Blake 1971, Barber and Blake 1981, MacDonald and Bourne 1987). For salinity, a negative correlation with MYI was observed but the influence of salinity in the transference of nutrients remained unclear.

Le Pennec and Beninger (1991) observed that through most of the energy supplied to the developing gametes comes from protein and glycogen reserves in the adductor muscle, there is also energy transference from the reabsorption of residual oocytes and from the transference of nutrients from the intestinal loop to the gonad. The intestinal loop penetrates into the gonad and has a digestive function (epithelium with intracellular and extracellular digestion) and there is a direct transference of the metabolites from the in-

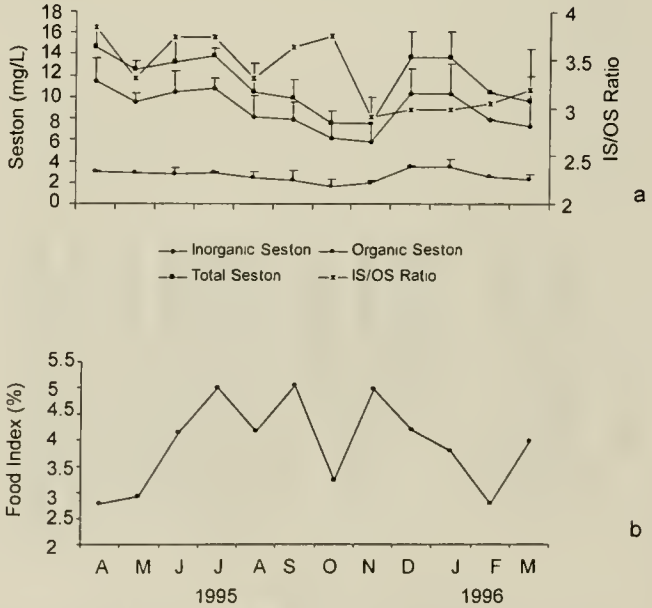

Figure 3. Changes in the seston and IS/OS ratio (a), and food index (b) throughout the annual cycle from the Rada del Puerto del Pichilingue, B.C.S., Mexico. (Error bars = SD).

testinal epithelium to the gonad and therefore to the developing oocytes. In this work, we found a lot of acid mucopolysaccharides in the intestinal loop, the mantle, and the perigonadal connective tissue of the developing gonads (male and female) of *A. ventricosus*. In the gonads, these carbohydrates can be the result of the transference from the intestinal loop (Le Pennec and Beninger 1991) or from the mantle (Barber and Blake 1983). In contrast, in the ripe gonad the acid mucopolysaccharides were few, so we believe that they were used in the maturation of the gametes.

In the developing and ripe oocytes, we observed a lot of glycogen that probably was the result of the transformation of the acid mucopolysaccharides. This carbohydrate is converted into triglycerides and is stored in the oocytes to be used as a future energy source for the larvae (Gabbott 1975). To support this, we found much unsaturated lipids (oil droplets) in the cytoplasm of developing and ripe oocytes.

The gross analysis of the seston or the measurement of a single chemical variable cannot describe fully the nutritive value of seston. To understand seston as food, it is necessary to determine its major biochemical constituents (lipid, protein, and carbohydrate) (Navarro et al. 1993). These components form the food material available for scallops and their larvae. TS, IS/OS ratio, and FI showed no clear relation to the reproductive cycle. It seems the reproductive cycle was influenced by a combination of the quantity of food and the muscle reserves.

A. ventricosus exists in large stocks in the bays of Baja California Sur (Tripp 1985, Aurioles-Gamboa 1992) but some of these stocks have been overfished (Chávez-Villalba and Cáceres-Martínez 1992, Cáceres-Martínez et al. 1993). This is true in Bahía de La Paz, in which the study area of this work is included. There is no fishery in this bay now because of the depletion of the *A. ventricosus* population. A management option is the culture of the species and this idea directed this study. From our results, we can say that the Rada del Puerto de Pichilingue is not an appropriate zone for the culture of catarina scallops. This is because the quality and quantity of food is poor and cannot support commercial production. Though reproductive activity was observed throughout the year as in other locations of Baja California Sur (Baqueiro et al. 1981, Villalejo-Fuerte and Ochoa-Báez 1993, Félix-Pico et al. 1995), the GSI values in the Rada del Puerto de Pichilingue were lower (2% less) than those obtained for *A. ventricosus* from Bahía Concepción, B.C.S., México (Villalejo-Fuerte and Ochoa-Báez 1993).

ABSTRACT We report the results of 2-year pilot scale scallop, *Placopecten magellanicus*, culture trials at Charles Arm, in Notre Dame Bay on the northeast coast of Newfoundland during 1989–1991. We used extrapolations of the growth and survival data from these trials, as well as records of all capital, labor, and operational costs, to conduct simulation modeling of cash flows associated with start-up and operation of scallop farms scaled up to commercial size. Our aim was to determine the economic viability of sea scallop farming in Atlantic Canada using the standard economic evaluation methods of Net Present Value (NPV) and Internal Rate of Return (IRR), based on production of 55–65 mm (shell height) live, whole, scallops using a suspended pearl net culture system. Two separate pilot trials were carried out concurrently. In the first, the effect of stocking density and culling on growth and survival were determined by stocking scallop seed in pearl nets at five different starting densities; 50, 75, 100, 150, and 200/net with subsequent culling (thinning) at two different times during grow-out. In the second trial, the effect of seed grading and net mesh size on growth and survival were determined by grading seed into two nominal sizes based on shell height, small (< 18 mm) and large (> 18 mm), followed by stocking in pearl nets of varying mesh size: 4.5, 6.0, and 9.0 mm, at a starting density of 50/net for grow-out. After 2 years of grow-out, size at age (growth) was significantly related to initial seed stocking density, culling, net mesh size, and seed grading. Survival was significantly related to initial stocking density, culling, and seed grading but not to net mesh size. The model simulations predict scallop farming enterprises with vertically integrated culture farms and processing plant operations, and with annual stocking rates of about 1 million or more seed per year, are economically viable in current market and financial conditions. Sensitivity analyses indicate farm business viability is relatively sensitive to changes in sale price received for harvested product, but relatively insensitive to changes in capital costs, labor, other operational costs, or to mortality. The simulations also predict farm ownership of a processing plant enhances the economic viability of farming enterprises. These favorable economic projections support the contention that continued private and government-assisted investment in expansion of a whole scallop culture industry in Atlantic Canada is warranted.

KEY WORDS: Scallop, *Placopecten magellanicus*, aquaculture, bioeconomics

INTRODUCTION

The sea scallop, *Placopecten magellanicus*, has been the mainstay of the traditional commercial scallop capture fishery in Atlantic Canada for many years. Beginning in the 1960s, considerable effort has been expended to explore the commercial aquaculture potential of the sea scallop (Couturier et al. 1995, Naidu et al. 1987) using technology, equipment, and rearing practices widely used in the extensive Japanese scallop culture industry (Taguchi 1977 Aoyama 1989) for the indigenous Japanese scallop, *Patinopecten yessoensis*. North American markets for scallop products have traditionally been almost exclusively restricted to the white adductor muscle, or "meats," as they are known in the industry. Early efforts to commercialize culture of the giant sea scallop, *Placopecten magellanicus*, in Canada's Atlantic provinces were based on production of meats intended to compete in these existing markets.

Development of the culture industry has been slow. Total annual Canadian production of cultured scallop has averaged < 100 mt since 1993 (Dept. of Fisheries and Oceans Statistics Rept. 1998). This figure includes both sea scallop, *Placopecten magellanicus*, production from Atlantic Canada as well as production of the introduced Japanese scallop, *Patinopecten yessoensis*, in British Columbia on Canada's West Coast. Two factors are considered to be primarily responsible for the slow increase in cultured production of Atlantic sea scallop: (1) industry dependence on annual wild seed collection that has proved to be unreliable with wide interannual fluctuations in seed settlement (Couturier et al. 1995); and (2) high production costs for meats that marginalized economic viability (Frishman et al. 1980, Gilbert 1987, Gilbert and LeBlanc 1991, Wildish et al. 1988).

These economic analyses, which focused on "meat" production as the sole source of farm revenue, cited high meat production costs as the principal obstacle to viability but did not consider the harvesting and sale of alternative products. However, markets are reported outside North America for "meats with roe," whole, live scallops and various "value-added" products. In Japan, a large-scale culture industry producing Japanese scallop, *Patinopecten yessoensis*, for sale in a variety of product forms, including whole, in-shell product has thrived for many years (Ikenoue and Kafuku 1992). Whole, in-shell queen, *Chlamys opercularis*, and king, *Pecten maximus*, scallops are marketed in several European countries (de Franssu 1990, Hardy 1991), but availability typically is restricted to markets near fishing ports, because scallops have a relatively short shelf life in air (De Franssu 1990). In British Columbia, live, in-shell, pink scallops, *Chlamys rubida*, and spiny scallops, *C. hastata*, < 80 mm in shell height have been supplied in small quantities (< 100 mt per annum) to both domestic and U.S. markets for several years (W. Heath, BC Min. of Fisheries, pers. comm.). Since 1996, this has been augmented by cultured scallop,

P. yessoensis, production, which has been sold throughout Canada, the U.S., and Asia. Cultured, in-shell sea scallops are also produced in small quantities (< 30 mt/annum) from farms in Nova Scotia and Newfoundland for sale into domestic Canadian markets.

Beginning in 1992, promotional and market development initiatives carried out by Thimble Bay Farms Ltd., have identified a niche market in Canada and the northeastern United States for a 55–65 mm SH (shell height) sea scallop product, sometimes termed "princess" or "cocktail" scallops by the seafood industry, depending upon its intended retail presentation. These are intended for retail and seafood service industry presentations similar to those in existing large volume North American markets for soft-shelled clam (*Mya arenaria*), steamers, littleneck, and cherrystone clams (*Mercenaria mercenaria*), and oysters (*Crassostrea virginica*) (De Franssu 1990). Sale of live, in-shell sea scallops now account for most of the annual farmed scallop production from the private company, Thimble Bay Farms Ltd in Newfoundland.

However, efforts to increase market volume have been limited by unavailability of product attributable in large part to production bottlenecks caused by unstable seedstock supply. This has limited total cultured scallop production in Newfoundland to 10–19 mt annually since 1994 (Dept. of Fisheries and Oceans Statistics Report, 1998). Recent construction of a new scallop hatchery at Belleoram in Newfoundland with an estimated annual production capacity of 20 million seed (G. Deveau, Nfld. Dept. Fisheries and Aquaculture, pers. comm.) may resolve the immediate seedstock supply problem and allow significant expansion in the industry. This has rekindled industry attention toward production and marketing issues, including whether it is economically advantageous to invest in market development for whole scallop products.

Harvest and sale of small, in-shell scallops, in particular, may have a dramatic effect on scallop farm viability. In the United Kingdom, harvest and sale of small (5–6 cm), in-shell queen scallop, *Chlamys opercularis*, is considered to be financially advantageous for scallop farmers, because it reduces labor costs associated with shucking meats and greatly shortens production time (Hardy 1991). This may also be true for sea scallop culture in Atlantic Canada. Recent consulting studies commissioned by the Provincial Government of Newfoundland and Labrador seem to support this contention (Atlantecon 1992, ARA Consulting Group 1993). Both studies developed financial projections suggesting the economic viability of commercial sea scallop culture might be enhanced, as compared to meat production, by developing markets for alternative products, particularly whole scallops < 70 mm in shell height.

The purpose of this paper, is to determine whether continued private industry and government investment in commercial expansion of this sector is warranted. In this paper, we report the results of pilot-scale sea scallop culture trials conducted at Thimble Bay Farms's leased acreage at Charles Arm in Newfoundland, Canada during 1989–1991. These trials sought to determine the biological, technological, and economic factors associated with producing for market a whole, in-shell scallop product using a Japanese suspended pearl net culture system. During the pilot trials, scallop growth and mortality, as well as labor, capital, and operating costs were recorded during a 2-year production cycle. Data collected during the pilot trials were used as input into a financial model to forecast the economic viability of commercial scale farms and, thus, provide both biological and economic bases for capital investment decision making for the Atlantic Canadian shellfish culture industry.

This paper has three goals: (1) to quantify the effects of stocking density, culling during grow-out, initial spat grading, and net mesh size on scallop growth and survival observed in pilot-scale culture trials and use these values to define the optimum husbandry techniques appropriate for future scaled-up commercial operations; (2) to conduct model simulations forecasting the economic viability of commercial-scale sea scallop culture farms utilizing production methodology similar to that used in the pilot trials to produce a 55–65 mm whole scallop; and (3) to assess the impact of vertical integration (e.g., farm ownership of a processing plant along with the culture farm) on projections of economic viability for scallop farming enterprises.

METHODS

Culture Trials

Pilot-scale culture trials were conducted at Charles Arm, in Notre Dame Bay on the northeast coast of Newfoundland. This site is one of two shellfish production areas leased by Thimble Bay Farms Limited, a private shellfish aquaculture company specializing in sea scallop and blue mussels. In October, 1989, 50,000 approximately 1-year-old sea scallop seed, originating from stocks in Port au Port Bay in western Newfoundland were purchased and transferred to the Charles Arm site. Scallop seed were stocked into standard 34-cm square Japanese pearl nets. The pearl nets were hung using a longline, suspended culture system in vertical arrays of 10 nets (Fig. 1). Each vertical array was repeated at 0.7-m intervals along a horizontal subsurface headline suspended at 3-m water depth and supported by surface floats.

Two separate trials were carried out concurrently. In the first, scallop seed were stocked at five different starting densities; 50, 75, 100, 150, and 200/pearl net. All nets were 6-mm mesh size. During the first year of culture in May, 1990, and again, in September, 1990, some of these nets were selected for culling (thinning), while others were left unculled. The nets originally stocked at 50/net were culled to 25/net, while all others were culled to 50/net. In the second trial, seed were graded into two sizes based on shell height, nominally referred to as small (< 18 mm) and large (> 18 mm). The graded seed were stocked in pearl nets of varying mesh size; 4.5, 6.0, and 9.0 mm, at a starting density of 50/net, with the exception of the small size grade which, because of their small size, could not be stocked into the 9-mm nets, because they readily fell through the mesh. All experimental trials were repli-

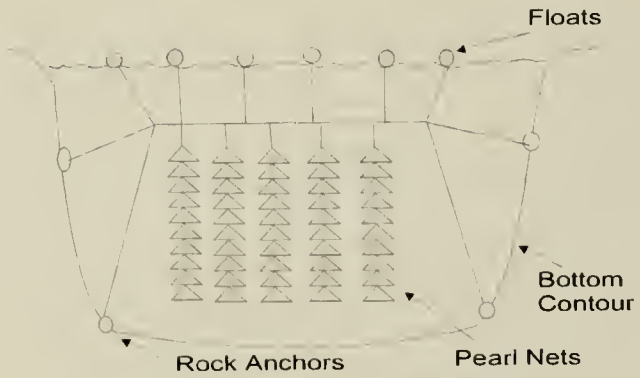

Figure 1. Diagrammatic cross-sectional representation of the longline scallop culture system used in the pilot trials at Charles Arm, Newfoundland.

cated such that each trial had a minimum of six pearl nets (sometimes as many as 10) in each category. In May and September of both 1990 and 1991 (September, 1990 and 1991 only for the size grade-mesh size trial), all pearl nets were retrieved and cleaned by a pressure washer, all scallops were measured for shell height, counted, and all mortalities were removed.

SAS statistical software (SAS Institute, Inc. 1985) was used for all statistical analyses of the biological data from the pilot trials. We used a nested, main effects analysis of covariance model (ANCOVA, SAS Institute Inc., 1985) to determine the relationships among stocking density, culling, size at age (shell height), and survival on each sampling date. Initial starting size of seedstock was the covariate to control for initial variation in shell height among pearl net groups.

Economic Model Parameter Selection

During the culture trials and including the post-trial harvest in September, 1991, records were kept of all capital and operational costs, as well as all labor incurred. These records, as well as the pilot trial growth and survival results, were used as input data to a spreadsheet-based Lotus™ financial model (Table 1) and extrapolated to commercial scale to simulate the startup and operational costs of commercial-scale farms and to forecast their economic viability using the standard financial evaluation methods of net present value (NPV) and internal rate of return (IRR) (Lusztig and Schwab 1977). All equipment, supply, and labor costs were sourced from commercial equipment suppliers as of March, 1999 and are quoted in Canadian dollars. Estimates of useful life span of various equipment were based on practical experience of Thimble Bay Farms. The purchase price of scallop seed and the sale price of harvested product are the most recent values quoted for Thimble Bay Farms, Ltd.

Selection of specific husbandry practices used in the models can have a major impact on the outcome of the model simulations. To ensure parameter values selected were as realistic as possible, we used the results from the stocking density-culling and net mesh-seed grade trials to select appropriate model input values for several key parameters. These included net mesh size, time to harvest for each seedstock cohort, the annual production cycle, stocking density, survival rate to harvest, and frequency of culling and handling for net cleaning.

Although a larger mesh size is expected to yield a faster growth rate, particularly in the second year of the production cycle, the 6-mm mesh is the largest mesh size capable of accommodating the smallest of the purchased seedstock (10–15 mm) in year 1. Any economic advantage attributable to slightly faster growth in 9-mm mesh nets, as compared to the 6-mm mesh, is outweighed by cost considerations because of the need to stock nets of two or more mesh sizes, the utility of which will vary annually, depending on interannual variations in shell height of the seedstock supply. Therefore, use of the 6-mm mesh size was assumed in the simulation modeling exercise.

The minimum time to harvest for each seedstock cohort was set at 15 months. Because the harvesting schedule must be year round, the annual production cycle from each annual seedstock cohort was set at January (year 2) to January (year 3) or, in other words, a 15–27 month production cycle. This production schedule was determined by analysis of the variability in the size at age data from the pilot trials.

Assuming no seasonality in the harvesting schedule, we selected the following stocking scenario for use in the model simulations: 50% of seedstock would be set at 25 scallops/net; 25% at 50/net; 25% at 75/net. Based on the growth data from the pilot trials, this stocking scenario should ensure year-round availability of a 55–65 mm product for harvesting and minimize the likelihood of scallops exceeding the maximum product size specification before being harvested. Although the pilot trials had no pearl nets initially stocked at 25/net, we consider the data from the 50/25 stock culled in May 1990 to represent a reasonable estimate of the probable growth performance of scallops initially stocked at 25/net for use in the model simulations. However, because scallops stocked at 25/net would exceed the maximum acceptable market size in less than 27 months, to ensure year-round availability of 55–65 mm product some seed scallops must be stocked at higher densities. Analysis of the variability in the size at age data from the pilot trials indicated unculled pearl nets initially stocked at 50 or 75 scallops/net best matched the required market size during the 15–27 month production cycle.

TABLE 1.

Selection of key model parameter values used in the economic model simulations.

Key Model Parameters	
Pearl net (square) specifications:	
Cage/mesh size	34 cm/6 mm
Stocking density (% of stock @ # per net)	50% @ 25
	25% @ 50
	25% @ 75
Net clean (# of times per year)	1
Culling/thinning of stock	None
Cost/life span (years) of capital equipment:	
Pearl nets (bulk order)	$1.80/10
Mainline, 365-m coil, 16-mm polypropylene	$98.60/8
Anchor and float lines, 365-m coil, 19-mm polypropylene	$233.10/8
Pearl net droplines, 365-m coil, 7-mm polypropylene	$29.00/8
Floats, 34 cm	$10.50
Floats, 200 L	$35.00
Work boat, 6.8-m aluminum	$9,400/15
Outboard motor, 40 hp	$3,695/5
Boat eqmt., star wheel and hydraulics	$4,000/5
Vehicle, ½ ton pickup with cap	$23,800/5
Processing plant/work shed, 9.3 × 6.2 m	$19,300/20
Plant water pumps	$2,000/5
Hourly labor rate	$8.50
Owner/manager's annual salary	$18,000
Per unit fuel cost (liter, gasoline)	$0.60
Unit cost of autumn-delivered Spat (10–25 mm)	$0.04
Survival rate to harvest	85%
Time to reach harvest size	15–27 months
Harvest schedule	Year Round
Product specifications:	
Market required product size (shell height)	55–65 mm
Ex-plant, per unit scallop sale price	$0.25
Business and startup fees (Year 1)	$9,205–11,505[a]
Crop insurance (per million stock)	$4,000
NPV discount rate (prime + 2%)	8.75%

[a] Varies with farm size.

Individual equipment costs were obtained from commercial supply sources. All other values were obtained from analysis of the pilot trial data or from Thimble Bay Farms Ltd. records.

In the pilot trials, all experimental groups with stocking of 50/net or less achieved survival rates > 85%. Most were > 90%. Therefore, we considered a survival rate of 85% to be a reasonably conservative estimate of survival for the model simulations.

Ideally, operational costs are minimized by selection of husbandry practices that allow individual scallops to be handled as little as possible during the production cycle. Because there are indications from the pattern of survival data, as well as from other concurrent farm operations, that excessive handling has a negative impact on survival, we chose no culling as the preferred production method for the simulations. This also lowered labor costs. For the model simulations, it also necessitated optimizing production solely by varying initial seed stocking density rather than by a combination of stocking density and culling.

The discount rate for NPV calculations was the small business cost of borrowing, as of March, 1999, used by the Canadian banking industry and is calculated as bank prime rate + 2%. A 50:50 split between bank loans and owner equity for capital infrastructure and equipment as well as an operating line of bank credit with a monthly repayment schedule of 3% of the outstanding balance is assumed.

Economic Model Simulations

We selected three hypothetical commercial farm sizes, based on annual seed stocking rates, for the model simulations: 500,000 (½ M), 1 million (1 M), and 3 million (3 M) seedstock per year. The half million size model represents a farm size consistent with a part-time or family operation worked as an income supplement; whereas, the other two represent possible full-time commercial-scale farms consistent with the amount of leased acreage currently utilized by shellfish farms in Newfoundland. Model simulations assume a year-round market requirement for 55–65 mm SH. live, whole product that is fully processed in accordance with all applicable Canadian seafood processing regulations in a farm-owned federally registered processing plant.

The spreadsheet-based financial model (Lotus™) forecasted the potential economic viability of each of these three model farm sizes using the NPV and IRR values. We used a sensitivity analysis procedure to simulate the effect of variability in specific model input parameters on the model output. For the sensitivity analyses, we used an iterative procedure, changing the value of the most important input variables (as a proportion of cash outflow) individually by a pre-set percentage until the NPV at year 10, NPV10 = 0.

To assess the effect of vertical integration (e.g., culture farm plus a farm-owned processing plant) on over-all economic viability of scallop farming enterprises, we recalculated the model simulations with the capital and operational costs of the processing plant deleted. This farm model requires assumption of sale of unprocessed scallops to an ex-farm seafood processor. We used an iterative process, adjusting the ex-farm price for harvested scallops in $0.005 intervals to determine the ex-farm price for unprocessed scallops needed to: (1) achieve minimal standards of economic viability (e.g., $0 < NPV10 < \$1000$; $8.75\% < IRR10 < 9\%$); and (2) achieve economic viability projections for farms without the processing plant comparable to those for the same size farm with the processing plant included.

RESULTS

Density and Culling Trials

At the outset of the culture trial, the mean shell height of all groups ranged from 19–21 mm (Fig. 2). Beginning with the first sampling in May, 1990, shell height was significantly related to stocking density ($P < 0.0001$). This relationship was maintained through all sampling periods. The pattern in least-square means (LSM) among the five initial stocking densities was also significant ($P < 0.01$ or greater) and consistent across all stocking densities ($LSM_{50} > LSM_{75} > LSM_{100} > LSM_{150} > LSM_{200}$).

Shell height was also significantly related to culling ($P < 0.0001$). The LSMs of culled (thinned) scallop groups were consistently larger in shell height than their unculled counterparts ($P < 0.0001$) at the same initial stocking density ($LSM_{cull\text{-}may90} > LSM_{cull\text{-}sep90} > LSM_{unculled}$). The interaction term of stocking density × culling date was also significant ($P < 0.0001$) throughout the sampling period. By the end of the second year of the trial (September 1991) an increase in shell height attributable to culling (Table 2) was noted at most initial stocking densities. In Fig. 2, the slope of the lines between adjacent sampling times indicate the mean growth rate during that interval. Growth rates were highest during the May to September period, 1990 (first summer season) and declined considerably thereafter. The highest mean growth rates, observed in the May 1990 cull group, ranged from 0.142 to 0.176 mm day^{-1}, depending upon stocking density, during this time.

The effects of initial stocking density and culling on survival were less consistent (Fig. 3). Survival was significantly related to both initial stocking density and culling date ($P < 0.0001$). However, the pattern in LSMs was inconsistent among initial stocking densities ($LSM_{50} = LSM_{100} = LSM_{150} > LSM_{75} > LSM_{200}$). LSM patterns with respect to culling date was also inconsistent ($LSM_{cull\text{-}may90} > LSM_{cull\text{-}sep90} = LSM_{unculled}$) although the May 1990 cull group were consistently larger than the other two groups. All except the unculled 200/net group had mean survival rates > 80% at the end of the pilot trials. Most exceeded 85%. Overall, the change in survival attributable to culling was much less pronounced than that for shell height among the experimental groups (Table 2).

Maximum growth was achieved in the 50/25 cull groups. In these groups, more than 90% of all scallops were greater than the minimum acceptable market size by May of Year 2 in the production cycle. Back-calculation of the size at age data from May in Year 2 (1991) based on the mean monthly growth rate during the September, 1990 to May, 1991 period projected that 90% of the 50/25 stock culled in May 1990 were probably in excess of the 55 mm minimum market size in January of Year 2 (1991). Thus, the minimum time to first harvest is approximately 15 months.

Seed Grading and Mesh Size Trials

We used a similar analytical approach to determine the relationships among seed grading and net mesh size with size at age (shell height) and survival. When graded, the mean shell height of scallop seedstock in the two nominal size grade categories were 15.3 mm (small grade) and 22.5 mm (large grade). At the end of Year 2 of the pilot trial in September, 1991, size at age was significantly related to both mesh size ($P < 0.0001$) and initial size grade ($P < 0.03$). The interaction term was not significant ($P > 0.05$). All groups exceeded 45 mm shell height by the end of Year 1 and exceeded 60 mm shell height by the end of Year 2 (Fig. 4a). Increasing mesh size had a positive effect on mean size at age for both size grades. However, the mean shell heights of small size grade groups were sometimes larger at the end of Year 2 compared to large size grade seed in nets of the same mesh size ($LSM_{9L} = LSM_{6S} > LSM_{6L} > LSM_{4.5S} = LSM_{4.5L}$).

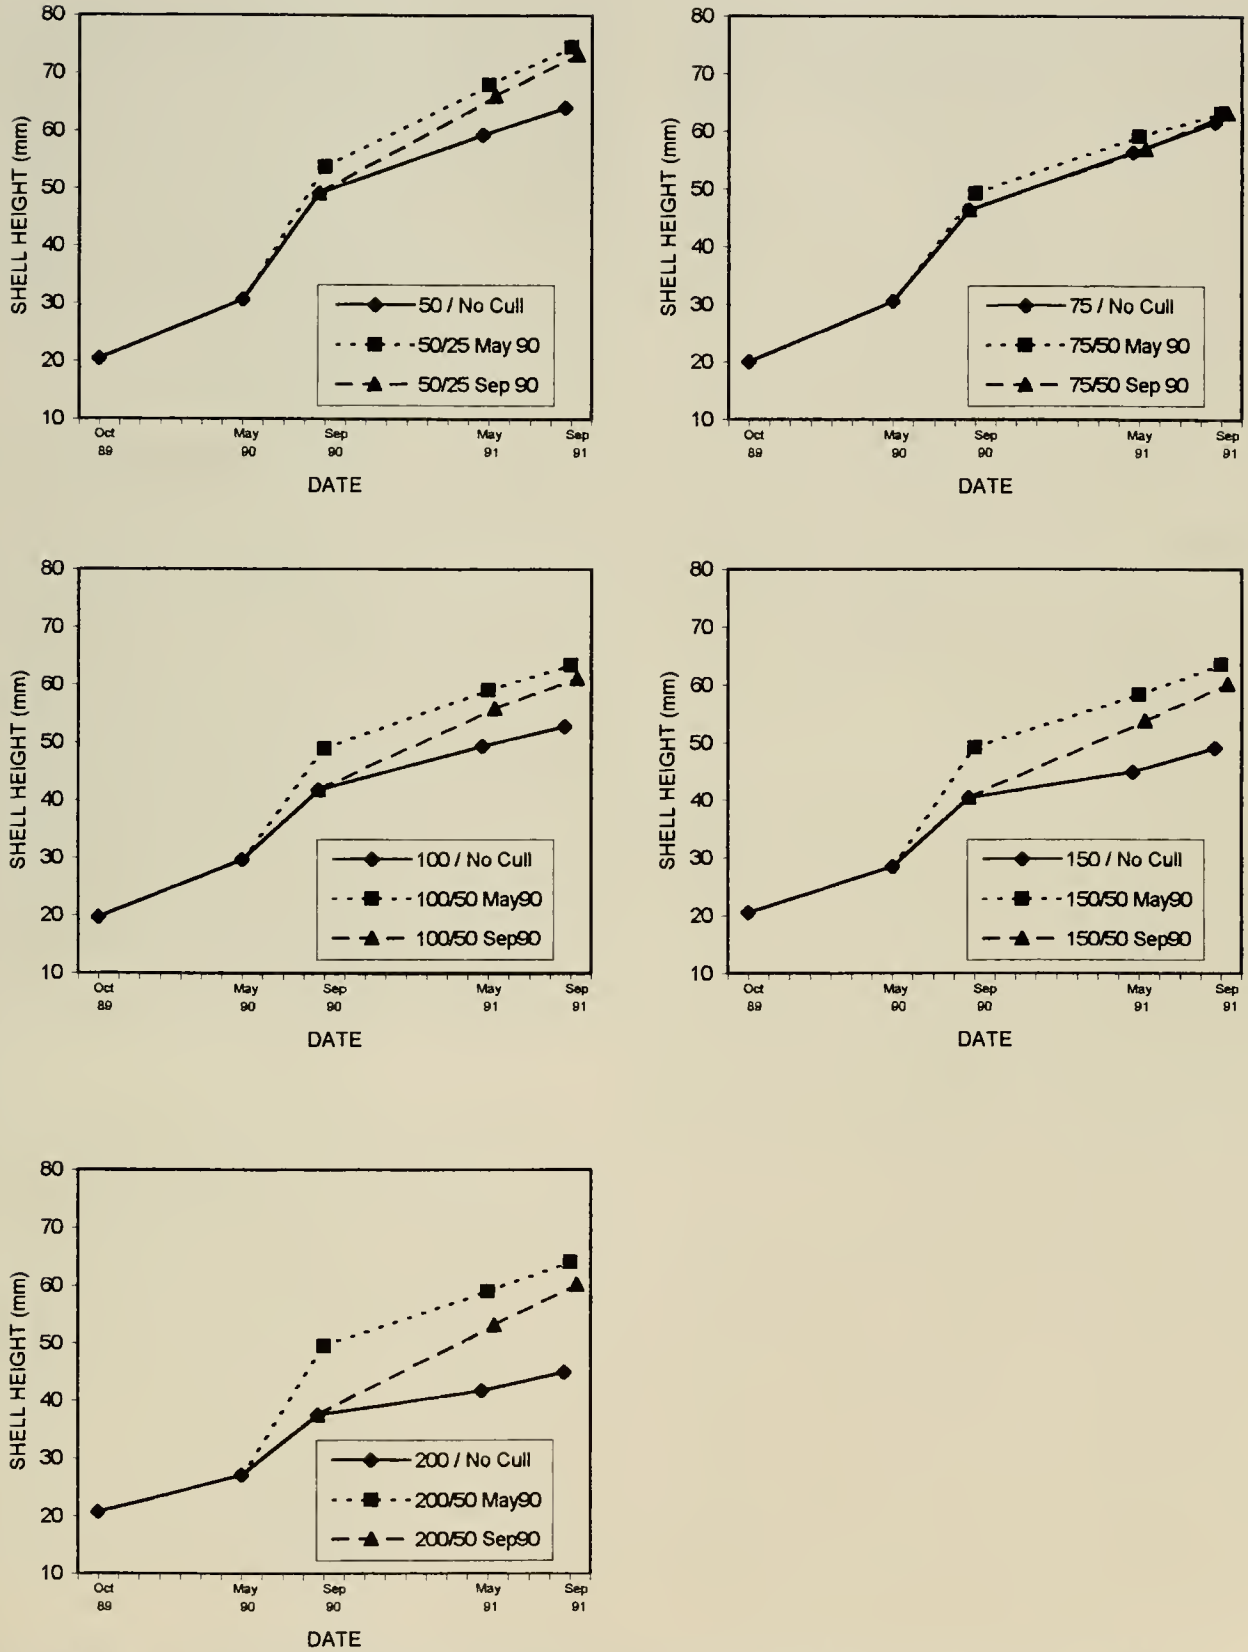

Figure 2. Mean size at age (shell height) over time of scallops in the stocking density-culling trials. The figure legends follow the convention "original stocking density / culled density, and date of culling" (e.g., 50/25 May90 means original stocking density = 50, culled density = 25, and May 1990 was the date of culling). Standard error bars (± 2 SE) are plotted but are obscured by the datapoints.

TABLE 2.

Percentage (%) change in mean shell height and mean survival at Year 2 attributable to culling in Spring (May) and Autumn (September) of Year 1, compared to the unculled stock of the same initial stocking density. Stocking density values are number of scallops net^{-1}.

	Shell Height		Survival	
Stocking Density	May Cull	Sept. Cull	May Cull	Sept. Cull
50	16.2	14.2	0.5	−2.7
75	2.5	2.6	12.0	5.3
100	20.2	15.7	−3.7	−6.7
150	29.4	22.7	0.1	4.4
200	42.5	33.9	24.4	5.7

Survival through Year 2 was not significantly related to net mesh size ($P > 0.05$) but was weakly related to initial size grade ($P < 0.04$). The small size grade experienced a relatively lower survival during the trials (Figure 4b) than did the large grade ($LSM_{9L} = LSM_{4.5L} = LSM_{6L} > LSM_{6S} = LSM_{4.5S}$). Survival through Year 2 in all groups exceeded 85%, while mean survival of the large grade exceeded 91%. In September, 1991, the observed mean size at age and mean survival of scallops in the mesh size-seed grade trials were comparable to those observed in the stocking density-culling trials.

Effect of Farm Size

The key parameter values used as input to the model simulations are given in Table 1. Net cashflow projections for all three farm sizes followed similar patterns of an initial cash investment in business startup (year 0), a further negative net cash outflow in the first year of operation, followed by a series of positive net cash inflows in subsequent years, the magnitude of which increased with increasing farm size (Fig. 5). Net present value (NPV) and internal rate of return (IRR) values derived from the model simulations indicate both the 1 M and 3 M farms are projected to be economically viable using a 10-year forecast horizon at present commercial bank interest rates and market prices (Figure 6). The smaller (½ M) farm size is not considered economically viable. The model simulations predict a trend of increasing NPV and IRR values with increasing farm size indicating the influence of "economy of scale" in farm operations.

Annual labor and seedstock acquisition costs represent > 50% of the total cash outflow for all farm sizes (Fig. 6). Acquisition of capital equipment and infrastructure is a relatively smaller proportion of cash outflow when annualized over the 10-year model simulation cycle. However, much of the cost for capital equipment and farm infrastructure are concentrated in Year 1 (processing plant, work boat, culture equipment, etc.). Labor and debt servicing costs as proportions of total cash outflow over a 10-year cycle do not vary with farm size. However, acquisition of capital equipment and operational costs both decline proportionally with increasing farm size; whereas, purchase of annual seedstock proportionally increases over a 10- year period. The payback period, defined as the time to recoup the initial investment assuming operating profits are retained within the business, is estimated at 4.2 and 3.4 years for the 1 M and 3 M farms, respectively.

Sensitivity Analyses

To determine how robust our viability projections from the model simulations were, we recalculated the simulations for the two model farm sizes deemed economically viable with the base input assumptions (1 M and 3 M farms). We used an iterative procedure, changing the value of each of the most important input variables (as a proportion of cash outflow) individually by a preset percentage until the NPV10 = 0. Projections of economic viability for both the 1 M and 3 M farm models are relatively insensitive to changing value assumptions for most major input variables, including capital, operational costs, and mortality (Fig 7). However, both models are relatively sensitive to changes in sale price. Reduction in sale price obtained for harvested product in the order of 20% and 28%, for the 1 and 3 M farms, respectively, reduced the NPV to zero. This is equivalent to a minimum sale price of $0.20 and $0.18/scallop, respectively.

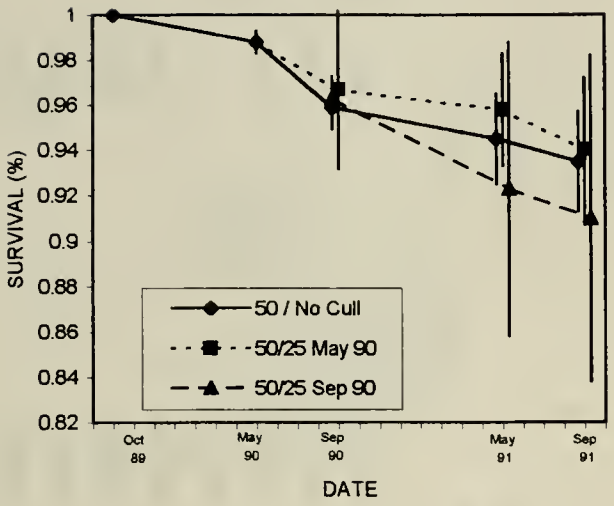
Effect of Farm-Owned Processing Capacity

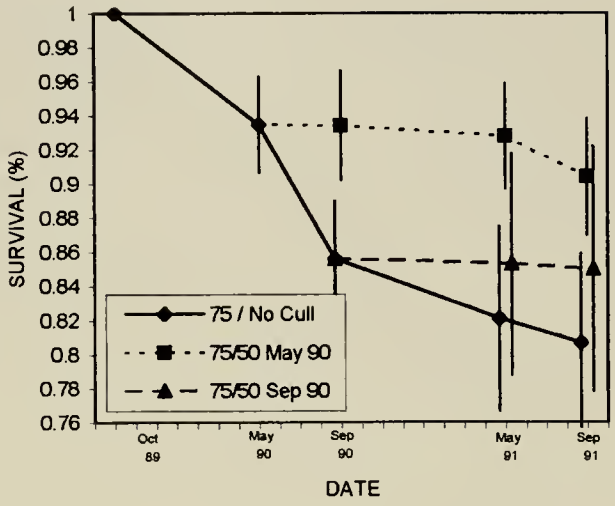
Without the processing plant, the ½ M farm is still not considered to be viable economically (NPV10 < 0; IRR10 < 8.75%) under assumptions of current scallop sale prices. Farms of this size only become marginally economically viable (e.g., 0 < NPV10 < $1000; 8.75% < IRR10 < 9%) if the ex-farm sale price for unprocessed scallops exceeds $0.26/scallop, a price that exceeds the current sale price for processed scallops. For the 1 M and 3 M farms without processing plants, economic viability becomes marginal as the ex-farm sale price for unprocessed scallops approach $0.185 and $0.165/scallop, respectively. To achieve economic viability projections comparable to those for farms with processing plants (equivalent NPV or IRR), the sale price for ex-farm unprocessed scallops must exceed $0.235/scallop for both the 1 M and 3 M farms, a difference of only $0.015/scallop for unprocessed versus processed scallops at current prices. Obtaining such a small price differential (approximately 6%) for sale of unprocessed scallops to an ex-farm processor may not be realistic, because it would seem to allow a rather small profit margin for the processor. With this considered, scallop farming enterprises with owner-operated processing capacity are likely more economically attractive than farms without owner-operated plants.

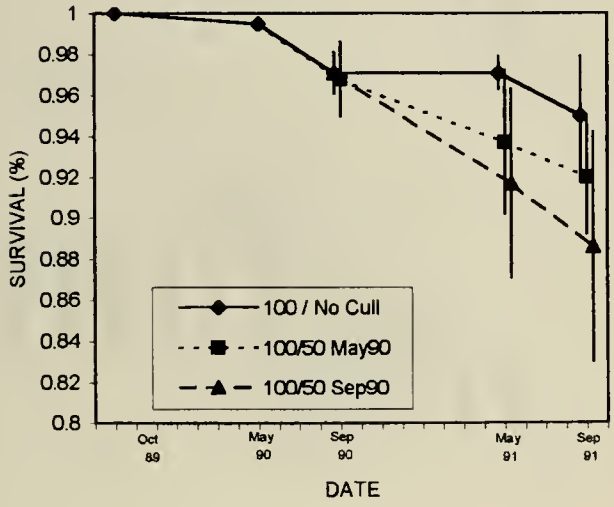
DISCUSSION

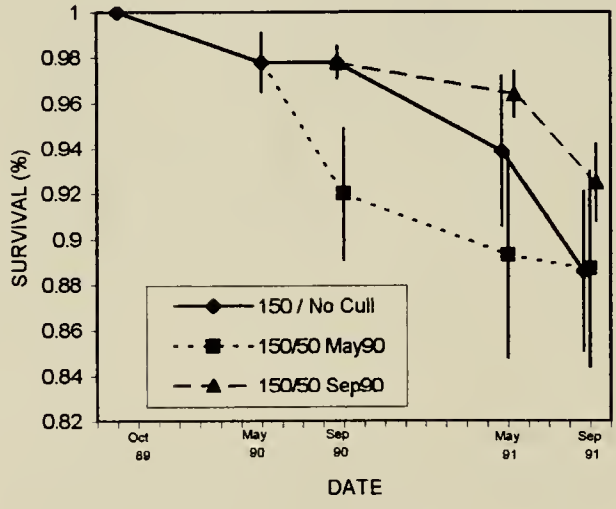
In commercial production systems, growth and survival are the two major biological rates of importance to cultured seafood growers. For bivalve mollusks, many factors influence these two variables. Some are environmental, such as food availability and water temperature, and others are physiological related to age, size, and reproductive maturity of the animals themselves (see Shumway 1991 for review). For suspended culture systems, additional stock husbandry factors must also be included, such as gear depth, type of gear and mesh size, current velocity, stocking density, and extent of biofouling (Claereboudt et al. 1994a, Claerboudt et al. 1994 b, Côté et al. 1993, Parsons and Dadswell 1992, Parsons and Dadswell 1994, Shellfresh Farms Ltd. 1993).

In this paper, we have examined the effect on scallop growth and survival of the major variables that can be readily manipulated by scallop farmers, assuming use of a basic pearl net culture system styled after the equivalent Japanese industry for the Japanese scallop, *Patinopecten yessoensis*. These are selection of stocking density, gear mesh size, culling (thinning) practices, and seed grading. In their review of sea scallop culture in Atlantic Canada, Couturier et al. (1995) considered stocking density the single most important factor affecting cultured sea scallop growth rates. Although it is difficult to compare growth rates, size at age, or sur-









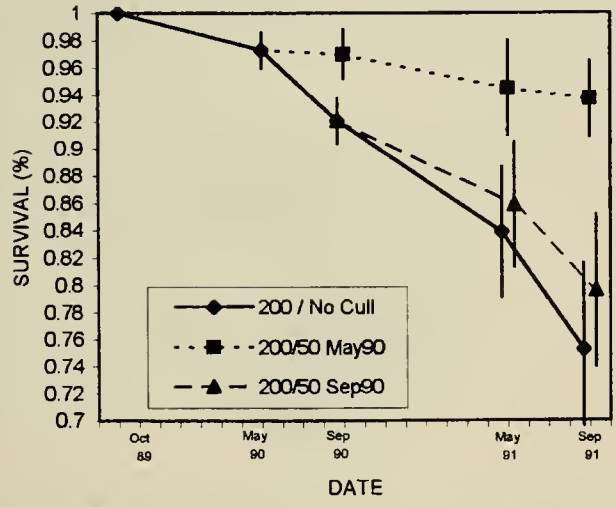


Figure 3. Mean survival over time of scallops in the stocking density-culling trials. The figure legends follow the convention "original stocking density / culled density and date of culling" (e.g., 50/25 May90 means original stocking density = 50, culled density = 25, and May 1990 was the date of culling). Standard error bars are ± 2 SE.

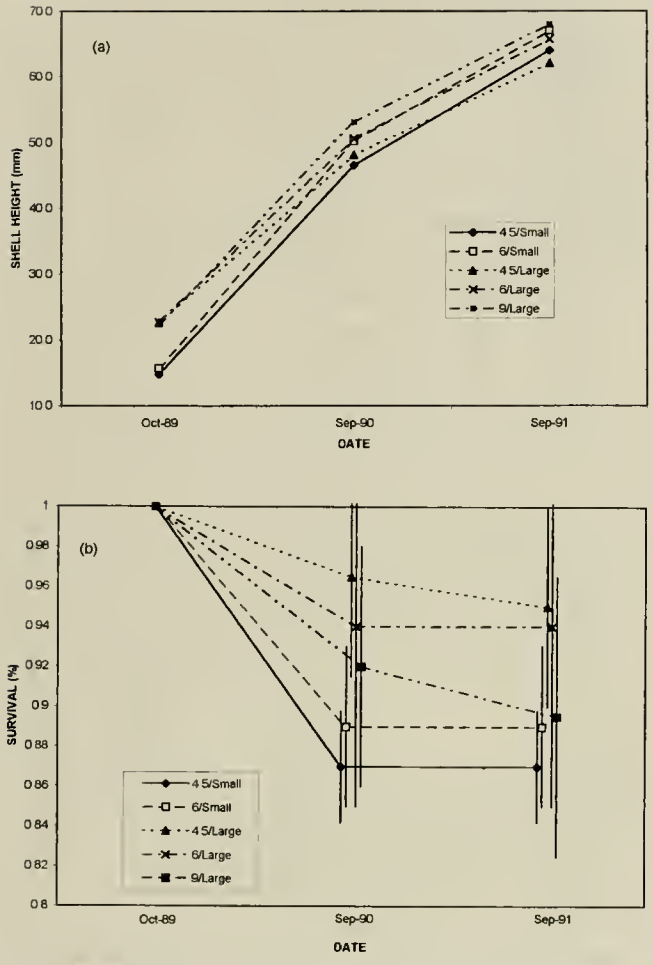

Figure 4. Mean size at age (shell height) and mean survival of scallops in the spat grading-net mesh size trials. The figure legends follow the convention "net mesh size in millimeters / nominal spat size grade at time of stocking" (e.g., 4.5 / small means mesh size 4.5 mm and stocked spat were small grade). Nominal spat size grades were < 18 mm (small) and > 18 mm (large). Standard error bars are ± 2 SE but are obscured by the datapoints in (a).

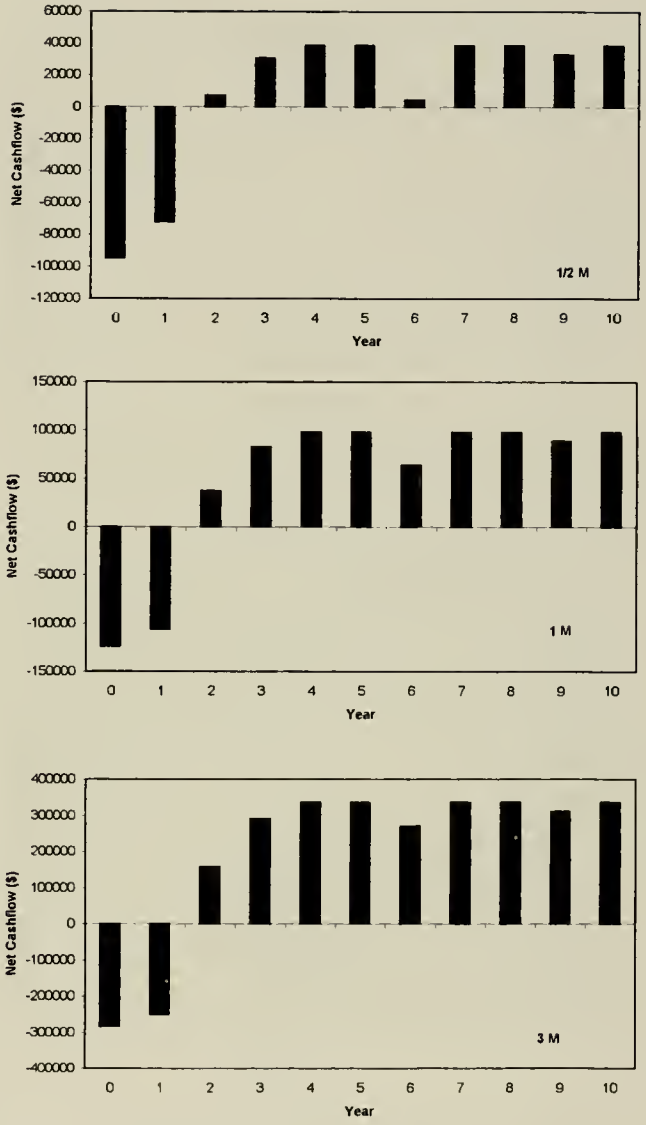

Figure 5. Annual net forecasted future cashflows over a 10-year period from initial startup for three sizes of sea scallop farms with farm-owned processing plant included: ½ million seed yr^{-1}, 1 million seed yr^{-1}, and 3 million seed yr^{-1}. Year 0 is the initial capital investment before startup.

vival data among different studies, gear, and locations, the growth and survival rates observed in this study seem consistent with those reported for sea scallops in suspension culture grown elsewhere in Atlantic Canada (Côté et al. 1993, Dadswell and Parsons 1991, Parsons and Dadswell 1992, Parsons and Dadswell 1994, Wildish et al. 1988).

In our study, size at age and survival varied with stocking density, gear mesh size, culling practices, and seed grading. Both size at age and survival tended to decrease with increasing stocking density, a result consistent with previous studies on several scallop species including the Japanese scallop, *Patinopecten yessoensis* (Yamamoto 1978, Ventilla 1982), the bay scallop, *Argopecten irradians* (Duggan 1973, Rhodes and Widman 1984), and the sea scallop, *Placopecten magellanicus* (Côté et al. 1993). However, Penney (1995), in a study of large scallops > 75mm shell height, did not find a significant relationship between stocking density and survival. Parsons and Dadswell (1992) also found survival in sea scallops from New Brunswick to be unrelated to stocking density. In the present work, nonrandom handling mortality, an artifact of our "batch processing" style sampling procedure, was likely implicated in the inconsistent survival patterns among the different density groups observed in the pilot trials. This might explain the anomalous high mortality among the 75/net groups. Similar instances of nonrandom apparent handling mortality among adjacent groups were noted periodically during the farm's other commercial operations. We, therefore, consider excessive or improper handling of gear to be a more important factor influencing survival than stocking density, a finding that would be consistent with that of other studies (Parsons and Dadswell 1992, Ventilla 1982, Wildish et al. 1988).

In this work, size at age in pearl net culture was improved by early culling and by increasing the initial net mesh size. Survival was also improved by early culling but was unrelated to net mesh size. Larger sized seed did not maintain their size at age advantage over small grade seed after 2 years of grow-out. This suggests shell height variation in 1-year-old seed scallops from wild sources is

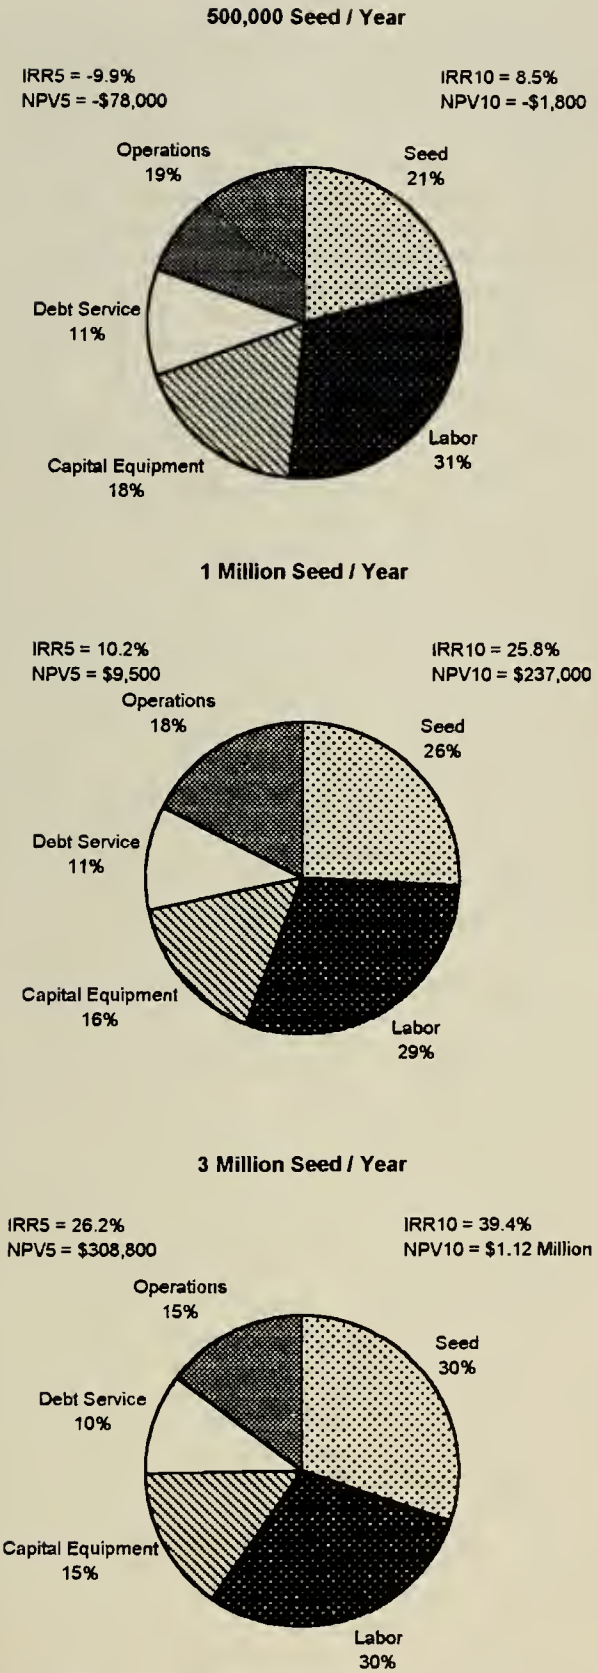

Figure 6. Mean annual cash outflows by category over a 10-year cycle, with NPV and IRR values for model simulations of three sizes of farm operations. (NPV5 = NPV calculated over 5 years, etc.). NPV and IRR calculations were based on cashflows from Figure 5.

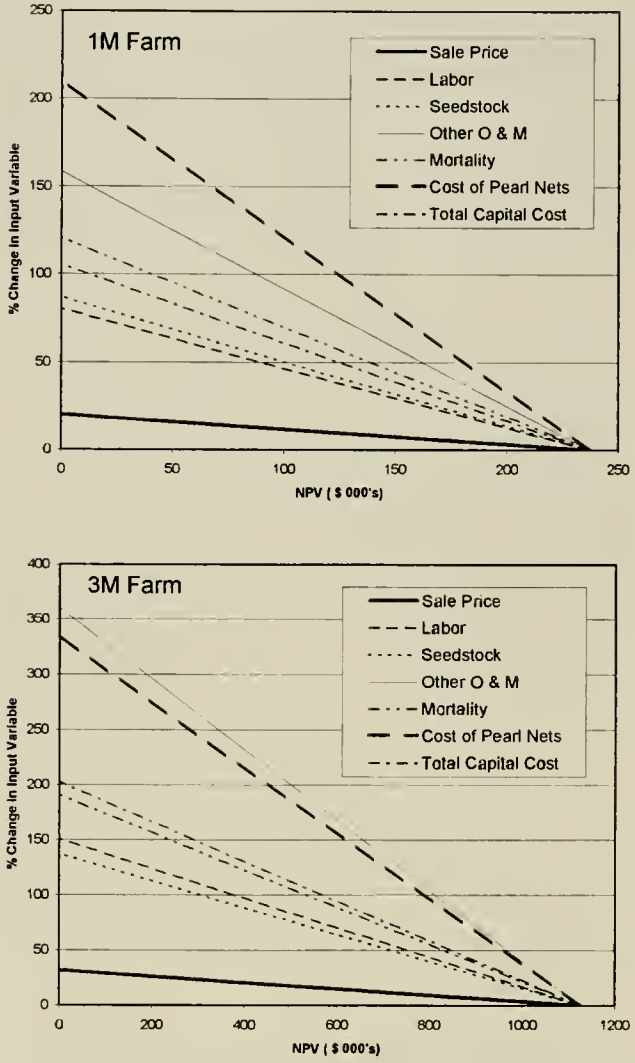

Figure 7. Sensitivity analysis of the effect of changing value assumptions of the major model input variables (reduction in sale price; increase for all cost variables and mortality) on projected NPV10 values (NPV calculated over 10 years) for the 1 M and 3 M farm models. Percentage change in input variables at NPV = 0 indicate the proportional change from the base values for each variable required to reduce NPV10 to zero.

likely the result of variation in environmental factors or seed collection husbandry practices rather than within population genetic variation. However, seed grading before initial stocking may have commercial value as a means to reduce size at age variation within individual pearl nets at harvest time.

Selection of production practices for the model simulations was guided by two general considerations: (1) the intended product was a 55 to 5 mm, whole, live scallop; and (b) harvesting and sale of product was required year-round with no seasonality in production volume. Ensuring year-round availability of a 55 to 65 mm product requires adjustment of farm production practices, including selection of stocking densities, deciding whether or not to cull and when, and selecting a harvesting schedule to minimize labor costs, while still meeting market demands. Variable stocking densities are required to ensure correctly sized stock are available for harvest throughout the year. Economic viability is optimized by early generation of sales revenue, achieved through timely harvesting.

However, harvesting should not be so early that within-net shell height variation is such that a significant proportion of scallops in harvested nets are under the minimum acceptable market size. This situation would necessitate the return of large numbers of undersized scallops to pearl nets for further on-growing, resulting in added labor cost.

It would seem unlikely that further minor changes to the basic pearl net culture system or husbandry practices are capable of affecting significant improvement in labor costs and, hence, the outcome of the model simulations. The sensitivity analyses indicate the viability of model farms is relatively insensitive to changes in capital costs, labor, or other operational costs. Further significant reductions in labor costs are likely to be achieved only by substitution to another culture gear entirely or by use of increased mechanization during farm operations. Parsons and Dadswell (1994) suggested that, although the initial capital cost of pearl nets was much lower compared to lantern nets, when handling times and their associated labor costs were factored in, lantern nets and Shibetsu nets gave the lowest over-all cost of production. However, this suggestion must be viewed with some caution. In a previously reported scallop rearing trial in Newfoundland using scallops > 75 mm shell height, scallops raised in pearl nets were larger than those raised in lantern nets at comparable stocking densities (Penney 1995). In the same study, survival was unaffected by gear type.

The reason for the better growth in pearl nets is unknown, but it may be attributable to differences in water flow (and, hence, food availability) around and within the two net types. All suspended net culture systems impede water flow, which, in turn, negatively affects production, a condition that is exacerbated by increased stocking density, reduced net mesh size, and biofouling (Claereboudt et al. 1994b, Devaraj and Parsons, 1997, Parsons and Dadswell 1994). Pearl nets are estimated to reduce water flow by 46–61% (Claereboudt et al. 1994b), but no comparative measurements are available for lantern nets. The better growth of scallops in pearl nets compared to lantern nets (Penney 1995) support selection of the basic pearl net system as the more appropriate net type compared to lantern nets. In addition, some growers find large lantern nets clumsy to handle from small boats similar to those used in our simulations.

Projections of economic viability derived from the model simulations indicate commercial sea scallop farms marketing a whole, 55–65 mm product can be profitable enterprises in Atlantic Canada. Our favorable projections are in sharp contrast to earlier economic analyses for culture systems based on production of adductor meats alone for sale into traditional North American scallop markets (Frishman et al. 1980, Gilbert 1987, Wildish et al. 1988, Gilbert and LeBlanc 1991).

These conflicting economic projections for in-shell versus meat production are likely because of a combination of factors. Revenues from in-shell product sales begin about 15 months after stocking in our model simulations. In contrast, production of meats in the 30–40 count range (North American scallop markets quote in number of pieces to make one pound weight) would require an extra 15 to 20 months of culture (Penney 1995; Penney and McKenzie, 1996) and would likely generate less ex-farm revenue per scallop at current North American market prices (Urner Barry 1999). This protracted culture time would also increase capital costs, because extra pearl nets and other gear are required for each annual seed cohort, as well as increase labor costs for stock thinning, gear deployment, and in-plant meat shucking.

In Newfoundland, only two companies are currently in commercial production although this will likely increase quickly, because a total of nine companies and 11 culture sites in various stages of development totaling nearly 400 leased hectares are now in operation (G. Deveau, Nfld. Department of Fisheries and Aquaculture, pers. comm.). Recent annual scallop production by the two farms currently selling cultured scallops has varied since 1994 from 10–19 mt, the majority of it marketed in whole form. Estimated annual production from a single 1 M farm would be about 17 mt. This is approximately 10–20% of all in-shell scallop products currently being sold in Canada from Canadian sources. Clearly, considerable developmental marketing initiatives would be required by industry to expand significantly North American market share for in-shell scallop products sufficient to absorb the production of a new Atlantic industry composed of several such farms. Alternatively, the potential for increased development of other international export markets into such countries as France, with an existing tradition of acceptance of alternative scallop products (de Franssu 1990) should be determined.

A trend of increasing NPV and IRR values with increasing farm size indicates significant economies of scale accrue to larger farms. Despite farm size, annual labor and seedstock acquisition costs are the largest factors in over-all annual cash outflows. The cost of labor has been previously recognized as an important component of over-all production costs for scallop culture (Atlantecon 1992, Parsons and Dadswell 1994). In our model simulations, labor is reduced through elimination of the need for culling during grow-out by selecting appropriate initial stocking densities. This tends to improve the over-all survival rate as well. Larger sized farms (1 M and 3 M models) are projected to be more profitable than smaller operations (½ M model).

In Atlantic Canada, many shellfish culture farms, particularly in mussel and oyster culture, have been started as "cottage-style" ventures operated on a part-time basis as a source of supplementary family income by persons employed in other industries. If started by families already employed in the fishing industry, economic viability forecasts using NPV or IRR calculations typically remove from consideration certain capital costs (e.g., cost of boat, motor, truck, ropes, etc.) that are shared with the fishing enterprise (e.g., Ridler 1995). These capital costs are considered to have been already compensated by the fishing enterprise. The ½ M model is sufficiently small in scale to be considered this way. If calculated using these assumptions, the ½ M model is forecasted to be economically viable (NPV = $34,000; IRR = 16.5%).

Of particular interest for industry development purposes, is the effect the owner-operated processing plant has on projected economic viability. Vertical integration and increased farm size are known to have a positive effect of the viability of other shellfish aquaculture operations (Adams and Pomeroy 1992, Lambregts et al. 1993). For scallop farming enterprises, irrespective of farm size, NPV- and IRR-based projections of economic viability changed only slightly with elimination of the owner-operated processing plant as part of the over-all enterprise. This is attributable to two factors. First, the capital investment in processing capacity is quite small for processing whole scallops (see Table 1). Because product processing of whole scallops consists of a fairly simple process of washing and cleaning shells, sorting empty shells, and packaging, a relatively small building with minimal equipment is needed. Second, the labor costs for such a simple processing operation are also relatively minor. Processing in-shell scallops

eliminates the need for shucking, which is the most labor-intensive component of in-plant scallop "meat" processing.

For either the 1 M or 3 M farms, comparable NPV and IRR values were projected for enterprises with and without processing capacity at a sale price difference of only $0.015 per scallop for ex-farm processed scallops versus ex-farm unprocessed scallops. It seems unlikely that ex-farm processing companies would pay to the farmer such a small price differential for unprocessed scallops, because this leaves them a very tight margin for their own capital and operational processing costs and potential profit. It is far more likely that processing companies would pay farmers a lower price for unprocessed scallops, which would have a negative impact on the economic viability projections for farming enterprises. Thus, incorporation of an owner-operated processing plant as part of the business venture would be likely to enhance business viability. Ex-farm prices for unprocessed scallops in the range of $0.16–$0.18/scallop would make scallop farming not economically viable under current conditions regardless of farm size. Nevertheless, product processing with subsequent direct sale of product to seafood buyers and brokers represents a level of business management and marketing activity that some prospective farmers may not choose to pursue. This may be especially true for the ½ M farm size model that may be a part-time or family operation.

Favorable NPV and IRR projections are not the only criteria upon which to evaluate the potential for success of any new business venture. It should be recognized that many other factors can and do influence individual business investment decisions that are not considered in NPV or IRR calculations. Other factors, such as timing of large cash outflows versus revenues, debt repayment schedules, other financing arrangements, personal, biological, legal, and regulatory considerations, all may vary on an individual business and location basis and may also affect the success of any business venture (Lusztig and Schwab 1977).

Both the NPV and IRR financial forecasting methods used in our analyses are based on the estimation of future cash flows generated by an initial capital investment and are commonly used as decision-making tools by financial analysts to guide investment in new businesses. Both give explicit consideration of the time value of money, incorporated through the discounting of cash flows, which is often related back to the cost of credit (borrowing) from banks. Accurate forecasting of future cash flows, the basis of successful NPV and IRR applications, is often a challenge (Lusztig and Schwab 1977) and cannot anticipate aperiodic potentially catastrophic events, such as disease outbreak, major loss of gear because of ice damage, etc. Despite these individual situational considerations, favorable general NPV and IRR values such as we have forecaste from our model simulations indicate the underlying potential profitability of sea scallop farming in Atlantic Canada. Our positive NPV and IRR projections for in-shell scallop farms indicate continued industry and/or government investment to encourage commercial expansion in this sector is warranted.

Sensitivity analyses indicate the forecasted profitability is fairly robust with respect to anticipated variability in capital and operating costs, and stock mortality, but is relatively sensitive to fluctuations in sale price for harvested product. This last point must be closely considered in the start-up of any commercial business venture of the scale outlined by the model simulations. Greatly increased product availability in the marketplace may exert downward pressure on prices, particularly in the presence of inadequate marketing efforts. Given the in-shell nature of the product, prices may not be affected by trends in market prices for traditional scallop meats, a critical point considering the continuing increase in Chilean and Chinese cultured meat production as well as past fluctuations in both price and supply of meats from the North American fishery (de Franssu 1990). In existing North American markets, an in-shell sea scallop product would be more likely to compete (and, hence, to be affected by price fluctuations) with soft-shelled clam (*Mya arenaria*), steamers, littleneck, and cherrystone clams (*Mercenaria mercenaria*), and oysters (*Crassostrea virginica*).

We consider further development of a sea scallop farming industry in Atlantic Canada to be constrained by four factors: (1) availability of a reliable large-volume annual seedstock supply at commercially acceptable prices; (2) market development necessary to substantially increase the current, small volume niche-market status of North American markets for whole, 55–65 mm products; (3) the reported short shelf life of live scallops (de Franssu 1990) and; (4) the long-term frequency and severity of shellfish site closures because of outbreaks of biological toxins. The first two are inextricably linked. Resolution of the seed supply problem that has plagued industry expansion for years (Couturier et al. 1995), possibly by increased hatchery production of seedstock, will greatly increase the volume and interannual stability of available harvested product and, thus, encourage greater market penetration of the 55–65 mm whole product. Large-scale markets for whole scallop products will only be developed when production volume is sufficient to warrant the required financial investment for promotional market development. However, live scallops are reported to have a relatively short ex-farm shelf life as compared to other molluscan shellfish such as clams, oysters, or mussels (de Franssu 1990). Increasing market volume for whole scallop products may require a shift from sale of live product to a frozen in-shell or other secondarily processed form. This would have a negative impact on our projections of farm enterprise economic viability unless accompanied by commensurate farm-gate price increases.

Ultimately, the limitation to increased production of whole scallop products in Atlantic Canada most difficult to mitigate may be that caused by the distribution, frequency, and prevalence of biological toxin outbreaks. Scallop species are well known for their propensity to sequester biological toxins in their mantle, roe, and hepatopancreas tissue at relatively high levels as compared to other bivalve species (Shumway and Cembella 1993; Douglas et al. 1997). Detoxification of affected scallops may be quite slow, exceeding several months in duration and be quite variable among individuals (Shumway and Cembella 1993). Frequent and severe toxin outbreaks may limit expansion of scallop farms to areas where toxin outbreaks are relatively infrequent and of short duration. Although this has been the case in Newfoundland, thus far, continued industry expansion, particularly elsewhere in the Atlantic Canadian provinces may be seriously impeded by toxic event considerations.

ACKNOWLEDGMENTS

We thank members of the Mills and Jewer families of Botwood, Newfoundland who willingly helped pick, sort, and otherwise handle scallops during the 2- year pilot trials as well as staff of Thimble Bay Farms, Ltd. for their patience and help with many of the labor costing activities. We especially thank Frank Corbett, DFO Economics Branch, St. John's for much advice and assis-

tance to set up and run the economic analyses. K. S. Naidu and J. Davis, DFO St. John's provided many useful comments on an earlier draft. Funding assistance for the pilot trials was provided by the Department of Fisheries and Oceans, St. John's, Newfoundland and by the Canada / Newfoundland Inshore Fisheries Development Agreement.

ABSTRACT Survival and ploidy of D-stage oyster larvae (*Crassostrea virginica*) were determined following the rearing of embryos exposed to CB dosages of 0.5 mg/L, 0.25 mg/L, and 0.125 mg/L for 10 minutes, with 0.05% DMSO and ambient seawater as controls. The experiment was replicated three times on the same day with the same procedures and partially stripping the same male oysters; different females were used for each replicate. CB dosage treatments began when 50% of the eggs reached PB1 (24–31 min). Embryos were reared for 48 h at ambient temperature and salinity. Resulting triploid percentages were 13% ± 6.7% (0.125 mgCB/L), 61.8% ± 6.2% (0.25 mgCB/L), and 68.2% ± 14.1% (0.5 mgCB/L). No significant difference ($P \leq 0.05$) in mean survival was found between the three CB treatments. Significant differences in mean survival between the three replicates implies variability because of different sources of eggs.

KEY WORDS: *Crassostrea virginica*, oyster, triploid, cytochalasin B, dosage

INTRODUCTION

Cytochalasin B (CB), a cytokinetic inhibitor, was first used to produce triploid *Crassostrea virginica* and *Crassostrea gigas* (Thunberg) over a decade ago (Allen 1986, Stanley et al. 1981). Optimal treatments; that is, those yielding high proportions of triploids, have been reported for *C. gigas*, based on temperature, dosage, time of application, and duration; namely, 0.5 mgCB/1mL dimethyl sulfoxide (DMSO)/L of seawater for 20 min at 25 °C, when 50% of the eggs were at meiosis I (Allen et al. 1989, Downing and Allen 1987). Because *C. virginica* is less fecund than *C. gigas* (Galtsoff 1964), there is more concern for egg survival. Lower dosages and treatment times of 0.5 mgCB/L for 15 min at 25 °C (Shatkin and Allen 1990) and 0.25 mgCB/L for 10 to 15 min, at 27 to 29 °C (Barber et al. 1992) were suggested to increase the survival of embryos while maintaining high yields of triploids.

We tested the feasibility of triploid *C. virginica* production in Louisiana, based on the premise that higher summertime meat yields resulting from triploidy could be profitable for the oyster industry. Triploid induction, using 0.5 mg/L CB, was variable with commercial size broods (≥ 4 million eyed larvae). During the first summer of commercial-scale production, survival of CB-treated embryos was ≤ 5% compared to ≤ 21% for diploid controls using stripped gametes. Differences between the salinity at our hatchery and salinities at sites where broodstock were obtained affected development time, in particular meiotic synchrony, and have been identified as major causes of this variation (Supan 1995).

The objective of this study was to investigate the effect of CB dosage (H_0:$\mu_{0.5mgCB} = \mu_{0.25mgCB} = \mu_{0.125mgCB} = \mu_{0mgCB}$; H_a:≠) on survival and triploidy induction in *C. virginica*, and to determine what component of the variability was attributable to females, held in identical environments.

METHODS AND MATERIALS

Survival and ploidy of oyster larvae were estimated after exposing embryos to CB dosages of 0.5 mg/L, 0.25 mg/L, and 0.125 mg/L for 10 min, with 0.05% DMSO and ambient seawater as controls. The experiment was replicated three times on the same day with the same procedures by partially stripping the same male oysters; different females were used.

Preparation of Gametes

Gametes were obtained for each replicate in a fashion similar to the method described by Allen and Bushek (1992). Oysters were collected from nearshore containers, opened, and their gender was determined microscopically using gonadal smears. Ripeness was visually recognized by the presence of prominent genital canals. Female and male oysters were placed in separate areas to avoid cross contamination.

Eggs were obtained from three ripe females, randomly chosen for each replicate. Females were individually dry-stripped (i.e., without using seawater) to ensure equivalent periods of hydration (defined as the length of time eggs are exposed to seawater after stripping) and simultaneous fertilization. The resulting eggs were pooled and washed of gonadal debris with filtered (1 μm) ambient (24‰) seawater (FAS) by passing them through a 75 μm Nytex screen onto a 15 μm screen. They were then resuspended for enumeration and brought to a volume of approximately 8 million in 1 L FAS. The eggs were allowed to hydrate for 60 min at 28 °C before fertilization and treatment.

Three male oysters were partially stripped for each replicate by scraping away only a portion of the gonad into a beaker and then covering the oyster with plastic wrap to prevent desiccation. Sperm from the three males was pooled in a beaker after being washed of gonadal debris by passage through a 15 μm screen.

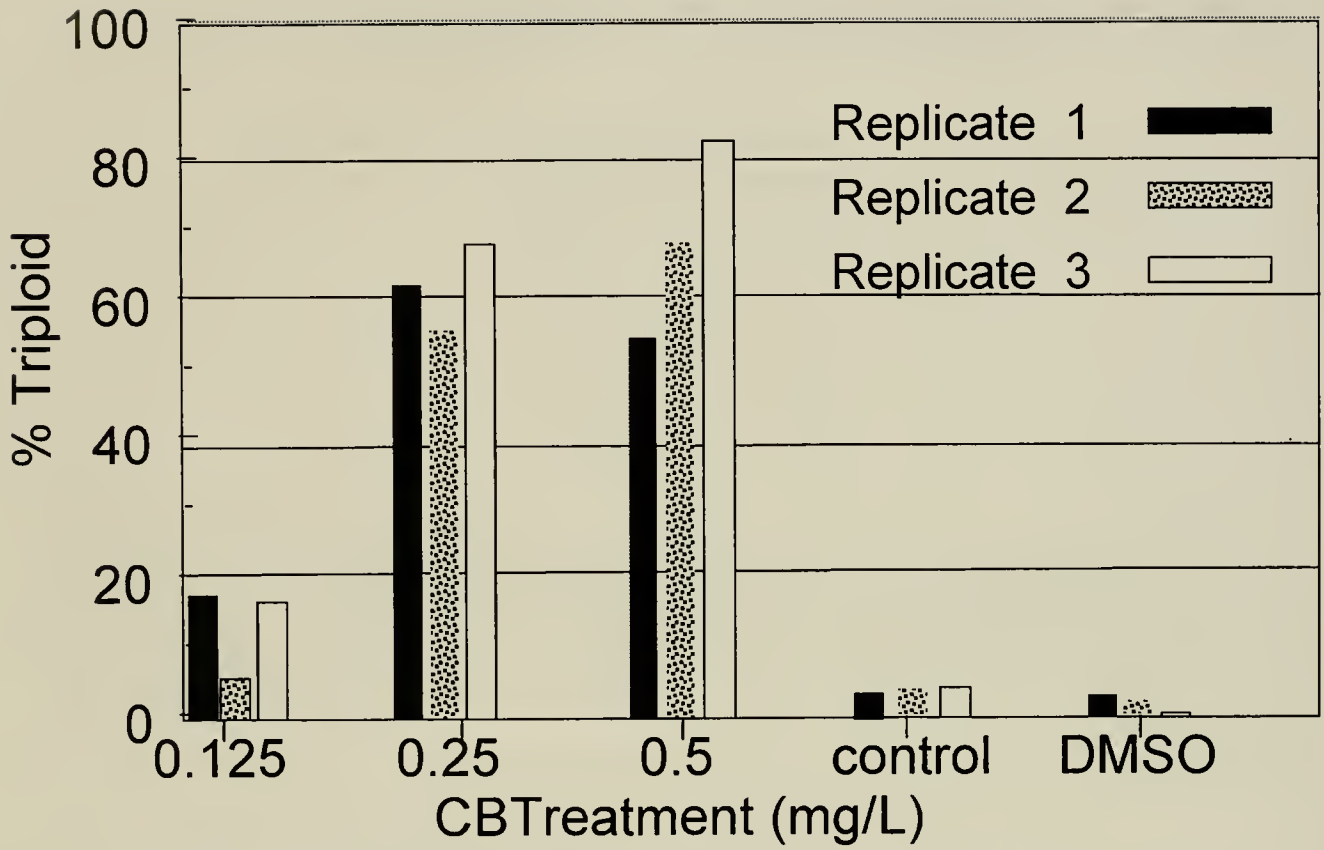

Figure 1. Percentage triploidy in *C. virginica* D-stage oyster larvae after treatment with cytochalasin B, by replicate.

Fertilization and Treatment

Pooled eggs were fertilized with approximately 10 sperm/egg and stirred regularly. After fertilization of the 8 million eggs, they were divided into five treatment beakers each containing 800 mL of FAS, bringing the eggs per treatment to about 1.5 M eggs/L. Eggs from individual beakers were examined microscopically for polar body formation at appropriate intervals. Treatments began when approximately 50% of the eggs reached PBI (24 to 31 min among replicates).

Treatments consisted of adding the appropriate aliquot of 1 mg CB/1 ml DMSO to the beakers of developing eggs to obtain dosages of 0.5 mg/L, 0.25 mg/L, and 0.125 mg/L. Our control consisted of 0.05% DMSO (*v/v*) dissolved in FAS and FAS alone served as a normal. Treatments lasted for 10 min. Afterward, each CB-treatment group of embryos was rinsed of CB with FAS over a 15 μm screen then placed in separate beakers containing 0.05% DMSO-FAS solution for 15 min. The embryos from each beaker were then rinsed of the DMSO solution and put into separate, labeled culture vessels containing 15 L of FAS for a final culture density of 15 embryos/L. Culture vessels were aerated and equal volumes *Isochrysis* aff. *galbana* clone CISO added. Embryos were incubated for 48 h at ambient temperature and salinity until they reached D-stage. All counts were obtained using triplicate 1 mL subsamples from each culture vessel. At 48 h, each vessel was individually drained onto a 40 μm screen, and subsamples were placed into 1.5 mL centrifuge tubes and shipped overnight to Rutgers University's Haskin Shellfish Research Laboratory for ploidy determination using flow cytometry.

** Tukey's honestly significant difference ($\alpha = 0.05$).
SD = Standard deviation.

Data Analyses

Differences among treatment means for survival and percentage triploidy were determined using analysis of variance (SAS 1991). Percentage triploidy was determined as a proportion of triploid cells among the total number analyzed by the curve-fitting program ModFit (Verity Software House, Topsham, ME) (Allen and Bushek 1992). Survival and percentage triploidy met the assumptions of normality and variance homogeneity after angular transformation (Dowdy and Wearden 1991). The models used survival and percentage triploidy as separate dependent variables and treatments and experimental replicates as independent variables. Tukey's Honestly Significant Difference Procedure was used to test the difference among the treatments and replicates ($\alpha = 0.05$).

RESULTS

Percentage triploidy and survival were not different between 0.5 mg/L and 0.25 mg/L CB treatments.

Percentage Triploidy

In treatments, mean percent triploidy was 13% ± 6.7% for 0.125 mgCB/L, 61.8% ± 6.2% for 0.25 mgCB/L, and 68.2% ± 14.1% for 0.5 mgCB/L. In controls, 1.4% ± 1.3% of the 0.05% DMSO treatment and 3.4% ± 0.3% of the FAS normal larvae were triploid. Figure 1 depicts percentage triploidy by treatment and replicate. Variation seems high among the three replicates; however, transformed data revealed no significant difference ($P < 0.05$).

The model (% triploidy = treatments, replicates) defined the relationship between the treatment effects and percentage triploidy and explained most of the variability ($R^2 = 0.9616$). Treatment was highly significant ($P < 0.0001$), and the replicate effect was not significant ($P = 0.5291$) (Table 1). *Post hoc* comparisons of mean percentage triploidy found neither significant differences between the 0.125 mgCB/L and the two controls, nor between the 0.25 mgCB/L and 0.5 mgCB/L dosages (Table 2).

Survival

Figure 2 shows survival by treatment and replicate. On average, the results demonstrate an inverse relationship between survival and CB dosage and a lack of effect (slight enhancement) with DMSO exposure. Although there was moderate variability among the replicates, overall, they all demonstrated the same trends across treatments.

The model explained a reasonable amount of variation in survival ($R^2 = 0.7172$). Both replicate and treatment were highly significant ($P < 0.0001$, Table 3). For treatments, both control and normal were the same, and all CB groups were the same (Table 4). Overall, CB groups had about 20% lower survival than did the controls.

DISCUSSION

These results support previously reported findings that 0.25 mgCB/L (Barber et al. 1992) and 0.5 mgCB/L (Shatkin and Allen 1990) are appropriate dosages for inducing triploidy in *C. virginica*. However, results are variable depending upon egg or sperm quality or some other factor (Allen and Bushek 1992).

Treatment Recommendations

We found no statistical difference in percentage triploidy or survival between the two higher CB dosages. Considering the cost

of CB ($10/mg in the U.S.), economics suggest that the lower effective dosage is preferable, at 28 °C for 10 min. However, with a range of 54 to 82% triploidy (0.5 mgCB/L) versus 55 to 67% (0.25 mgCB/L), one is inclined to use the higher dosage. Greater triploidy might have resulted from a longer (15 min) treatment time, at the sacrifice of lower survival. For maximum triploid production, embryos should be exposed to CB for a period of time long enough to have a high proportion captured at PB1 extrusion but short enough to minimize mortality (Barber et al. 1992). Allen and Bushek (1992) attributed low variance in triploid production to using meiosis I as a benchmark to begin treatment, claiming to have effectively removed meiotic rate as a factor. Although the time of initiation is determined by an appropriate developmental milestone (i.e., 50% PB1), the duration is fixed and does not accommodate varying meiotic rates. We suggest that appropriate duration of treatment be addressed by using a developmental benchmark to cease treatment as it is used for beginning it. Observation of a subsample of eggs, held at the same temperature but without treatment, could provide such a cue. Although this cue must be determined empirically, we suggest 2–5% cleavage might be appropriate. This benchmark could be used for *C. virginica* or any bivalve species.

The real solution to improving efficiency of triploid production is the development and use of tetraploid broodstock. Tetraploid male oysters produce diploid sperm; when used to fertilize eggs from diploid females, 100% triploid offspring result (Guo and Allen 1994).

ACKNOWLEDGMENTS

We are grateful to Jordan Bradford, Lee Hanson, the late Tony Venterella and his wife, Gayle, and the late Carlo Venterella for their logistical support during the project, and Mr. Ron Becker for his guidance and insight. We are also grateful to Wilbert Collins, Jules Melancon, and Al Sunseri for their donation of broodstock. Financial support was provided by grants from the Louisiana Board of Regents [LEQSF (93-96)-RD-B-08] and the Louisiana Sea Grant College Program [NA89AA-D-SG226].

ABSTRACT Lipid spray beads (SB) were prepared containing 13% w/w particulate riboflavin. Beads suspended in seawater lost 73% riboflavin after 24 h. Release of riboflavin from SB ingested by Pacific oyster (*Crassostrea gigas*) larvae was observed under epifluorescent light. Riboflavin concentrations in tissues of adult oysters fed on riboflavin-SB were significantly (SNK; $P < 0.05$) greater than those of oysters fed on seawater-filled SB. Concentrations of riboflavin in oysters exposed to dissolved riboflavin were not significantly greater than those of oysters fed on seawater-filled SB, indicating that elevated riboflavin concentrations in oysters fed on riboflavin-SB were attributable to breakdown of ingested beads rather than uptake of dissolved riboflavin leaked from SB into the culture medium. SB seem to be a promising means of delivering water-soluble nutrients to bivalve suspension feeders

KEY WORDS: Spray beads, lipid, riboflavin, oyster, larvae, *Crassostrea gigas*

INTRODUCTION

Little is known of the nutritional requirements of bivalve mollusks despite their obvious importance in aquaculture and natural ecosystems. The main reason for this lack of knowledge is that nutritionally satisfactory, defined artificial diets are not available. The development of microparticulate diets that both retain dietary ingredients when suspended in seawater and are digestible by bivalve mollusks has been a difficult goal to achieve. High surface area to volume ratios of microparticulate diets together with low molecular weights of essential nutrients, such as water-soluble vitamins, results in their rapid loss. For example, López-Alvarado et al. (1994) reported that > 80% amino acids were lost from microgel particles after only 2 minutes in aqueous suspension.

To address the problem of rapid loss of water-soluble nutrients from microparticulate feeds, Langdon and Siegfried (1984) developed lipid-walled microcapsules for the delivery of water-soluble vitamins to juvenile oysters (*Crassostrea virginica*). Later Buchal and Langdon (1998) and Langdon and Buchal (1998) developed lipid spray beads (SB) for the delivery of water-soluble nutrients and therapeutic substances to bivalves. Buchal and Langdon (1998) found that it was important to soften the walls of lipid-walled capsules and SB by adding 40% w/w fish oil to the tripalmitin walls of the particles in order to make them digestible by clams (*Tapes philippinarum*); however, softening the walls of SB in this way lowered 24-h retention efficiencies for encapsulated riboflavin from 97.9 to 85.1% (Buchal and Langdon 1998).

Seguineau et al. (1996) reported that the microalgal species *Isochrysis galbana*, *Pavlova lutheri*, and *Skeletonema costatum* contained high concentrations of riboflavin and thiamine; however, the concentrations of these two vitamins in scallop (*Pecten maximus*) larvae fed on a mixture of these algal species declined during growth and development. Seguineau et al. (1996) suggested that microencapsulated supplements of riboflavin and thiamine could be used to study the requirements of scallop larvae for these vitamins.

In this paper, we describe the results of feeding experiments in which larval and adult oysters (*Crassostrea gigas* Thunberg) were fed on SB containing particulate riboflavin to evaluate the potential usefulness of SB in delivering low-molecular weight, water-soluble nutrients to bivalve mollusks.

METHODOLOGY

Spray Beads

Preparation of Spray Beads Containing Riboflavin

Spray beads were prepared containing micronized, particulate riboflavin (Sigma) based on the method described by Buchal and Langdon (1998). Briefly, riboflavin crystals were ground to a fine powder (< 5-μm particles; McCrone micronizing mill, McCrone Scientific Ltd). Two grams of ground powder were mixed by sonication at 90 °C with 8 g of a lipid mixture made up with 4.8 g tripalmitin (Fluka Chemical Co.) and 3.2 g of menhaden oil (light cold pressed; Zapata Haynie Ltd.). The heated mixture was then forced under pressure (90 psi) through at atomizing nozzel (SUE-25B; Spraying Systems Ltd.) supplied with pressurized nitrogen at 10 psi. The beads were collected in a stainless steel cylinder cooled with liquid nitrogen then stored in the dark at −20 °C until use.

Determination of Encapsulation Efficiency

To determine encapsulation efficiencies, 10 g of SB were first dissolved in 3 mL chloroform and the vitamin core material extracted by addition of 3 mL distilled water with shaking. The aqueous supernatant was removed and the extraction repeated three times. Aqueous extractions were combined and the concentration of dissolved riboflavin determined spectrophotometrically (absorbance at 267 nm).

A subsample of 0.5 mL of chloroform was removed from the capsule extraction and transferred to a dry, tarred weighing boat. The chloroform was removed by heating for 24 h at 50 °C, and the boat was reweighed to determine the weight of extracted lipid.

Encapsulation efficiencies were expressed as the weight of encapsulated vitamin (mg) per 100 mg of lipid.

Retention of Riboflavin by SB Suspended in Seawater

Retention of riboflavin by SB was determined by measuring the proportion of initially encapsulated riboflavin remaining after 24 h suspension in seawater. To prepare SB for a leakage experiment, beads were first suspended in 2% polyvinyl alcohol with sonication. SB were then sieved using a 40-μm sieve, and beads under 40 μm were collected on a GF/C filter and rinsed with cold (5 °C) distilled water. The beads were then washed from the filter with cold distilled water and collected in a sealed vial and stored at 5 °C in the dark.

At the start of a leakage experiment, 75 to 100 mg of the sieved (< 40 μm) SB were suspended in 15 mL seawater (20 °C) by vigorous shaking. Immediately after suspension (t = 0), 1 mL of the bead suspension was taken and filtered onto a GF/C filter. The filtered SB were then washed with 1 mL of chilled (5 °C) seawater. The filtrate and washings were pooled and stored in the dark at 5 °C for analysis. Riboflavin concentrations were determined as described above. The remainder of the SB suspension was placed on a continuous agitator at 20 to 22 °C. Samples of suspended SB were taken over a period of 24 h to determine changes in the retention of riboflavin over time. Retention efficiency (RE) was defined as

$$\mathrm{RE} = \frac{\text{riboflavin retained on the filter}}{\text{riboflavin on filter and in filtrate}} \times 100$$

Breakdown of SB and Release of Riboflavin by Larvae

Feeding experiments were conducted to determine if oyster larvae could ingest and breakdown SB, thereby releasing riboflavin into the digestive system. Broodstock oysters were spawned, and the resulting larvae were raised on a mixed diet of *Isochrysis galbana* (T-ISO) and *Chaetoceros calcitrans* (Breese and Malouf 1975). After 8 days of culture, larvae were sieved onto a 45-μm screen, divided into two groups and each resuspended in two liters of seawater at a density of 10 larvae per mL.

Riboflavin-SB at a concentration of 50 SB/μL were fed to one group of larvae with gentle aeration to maintain SB in suspension. After 1 hour, larvae were sieved from suspension using a 45-μm sieve, rinsed with seawater, then resuspended in two liters of filtered seawater and fed on T-ISO alone for 2 hours. The larvae were then sieved from the culture medium and preserved with 0.5% formaldehyde (final concentration made up in seawater, buffered at pH 8.0 with borax) for microscopic analysis. The second group of 8-day old larvae were fed on T-ISO alone for 2 hours, then sampled and preserved for microscopic analysis (as described above).

Sampled larvae were examined using an epifluorescent microscope (Leica DMRBE; excitation 355–425 nm, emission 525 nm) at ×400 magnification. Green and yellow fluorescence indicated the presence of dissolved and particulate riboflavin, respectively, while red fluorescence indicated the presence of chlorophyll derived from ingested algae.

Breakdown of SB and Uptake of Released Riboflavin by Adults

An experiment was carried out to determine if adult oysters could breakdown ingested SB and absorb released vitamin into the hemolymph and tissues. Three groups of six adult oysters were separately held in 20 L of seawater and fed for 6 hours on T-ISO at a concentration of 50 cells/μL in combination with one of the following additions:

1. 20 riboflavin-SB/μL (equivalent to a concentration of 1.15 mg riboflavin/L or a vitamin dose of 3.8 mg riboflavin/oyster);
2. 20 seawater-filled SB/μL; or
3. dissolved riboflavin at the same concentration provided in 1.

Two grams of riboflavin-SB were suspended in distilled water, and the suspension was then poured through a 20μm mesh sieve. SB smaller than 20 μm were collected and filtered onto a GF/C filter, rinsed, and resuspended in 10 mL of distilled water. Aliquots of 100 μL SB suspension were taken to determine riboflavin and bead concentrations. Riboflavin concentrations were determined as described above. SB concentrations were determined using a Coulter Counter (Model TA2). Seawater and food additions were replaced every 2 hours over a period of 6 hours. The cultures were gently aerated to maintain beads in suspension.

After 6 hours, oysters were removed and dissected. Hemolymph samples were taken with a syringe from both the heart and the sinus of the adductor muscle. Samples of stomach contents were removed with a Pasteur pipette inserted through the mouth. Tissue samples of mantle and adductor muscle were also removed. The samples were frozen at −20 °C for protein and riboflavin analysis.

Riboflavin and Protein Analysis

Hemolymph samples were centrifuged, and riboflavin concentrations of the supernatant fraction were determined by high-pressure liquid chromatography (HPLC) (Seguineau et al. 1996). Mantle and adductor muscle samples were ground in 0.2M HCl and 0.6N perchloric acid (PCA) and centrifuged. Supernatants were then removed, their volumes adjusted to 2 mL with distilled water and riboflavin concentrations determined by HPLC (Seguineau et al. 1996).

Protein concentrations of hemolymph samples were determined by the method of Bradford (1976), using bovine serum albumen as a standard. Treatment of adductor muscle and mantle samples with HCl and PCA for the extraction of riboflavin probably resulted in the precipitation of most proteins in these samples; therefore, Bradford assays indicated concentrations of PCA-soluble protein and peptides in muscle and mantle samples. Riboflavin concentrations were expressed in terms of ng riboflavin per mg protein in tissue samples or per mL of stomach extract.

Statistics

The rate of loss of riboflavin from SB suspended in seawater was analyzed by regression analysis. Riboflavin concentrations in oyster samples from the three experimental treatments were compared by analysis of variance (ANOVA) (Model III; Super ANOVA, Abacus Concepts). Concentrations were log-transformed to ensure homogeneity of variances, as determined by plots of residual values against fitted values. If ANOVA indicated a significant treatment effect on riboflavin concentration, individual treatments were compared by Student–Newman-Keuls (SNK) multiple range test (significance level $P < 0.05$).

RESULTS

Encapsulation and Retention Efficiencies

SB were found to have an encapsulation efficiency of 13% w/w (mg riboflavin per 100 mg lipid). Leakage experiments indicated

that almost half the encapsulated riboflavin was lost from SB during the first 3 hours of suspension in seawater, followed by a more gradual loss over the subsequent 21 hours (Fig. 1). Approximately 27% of the initially encapsulated riboflavin was retained after 24 hours of suspension, equivalent to 3.5 mg of riboflavin retained per 100 mg of lipid.

Regression analysis indicated that there was a significant (P = 0.0012) relationship between the log of the fraction of riboflavin retained and the duration [log time (h)] that SB were suspended in seawater (Fig. 1). The rate of loss of riboflavin could be expressed in terms of the equation:

Log fraction retained = $-0.116 - [0.333 \times \log \text{time (h)}]$ r^2 = 0.994

Breakdown of SB and Release of Riboflavin by Larvae

Larvae were able to ingest and breakdown SB, liberating encapsulated riboflavin into the digestive system. Free riboflavin was observed as a diffuse greenish fluorescence in the guts of larvae fed on SB, and riboflavin crystals present in intact or partially digested SB were evident as bright yellow points (Fig. 2). The digestive systems of larvae fed on algae alone fluoresced red because of the presence of chlorophyll from ingested algae but no yellow or green fluorescence was evident (Fig. 2).

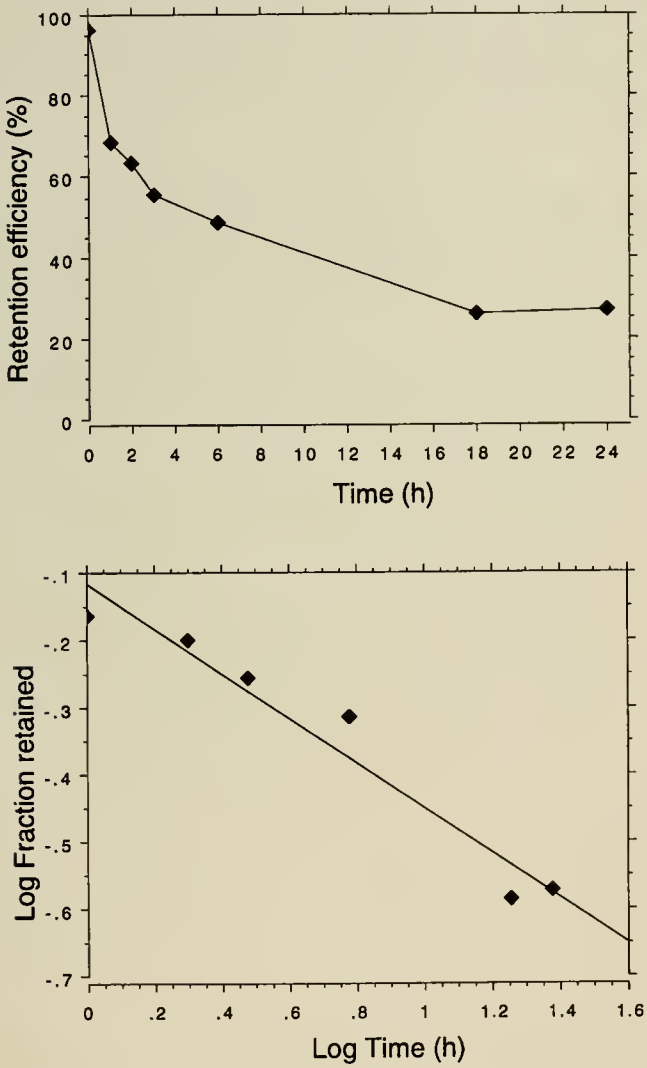

Figure 1. Retention of riboflavin by lipid spray beads suspended in seawater. Top: Change in percentage riboflavin retained by beads over a 24-h period Bottom: Relationship between log of fraction retained and log time duration of beads suspended in seawater. Log fraction retained = $-0.116 - [0.333 \times \log \text{time (h)}]$; $r^2 = 0.994$

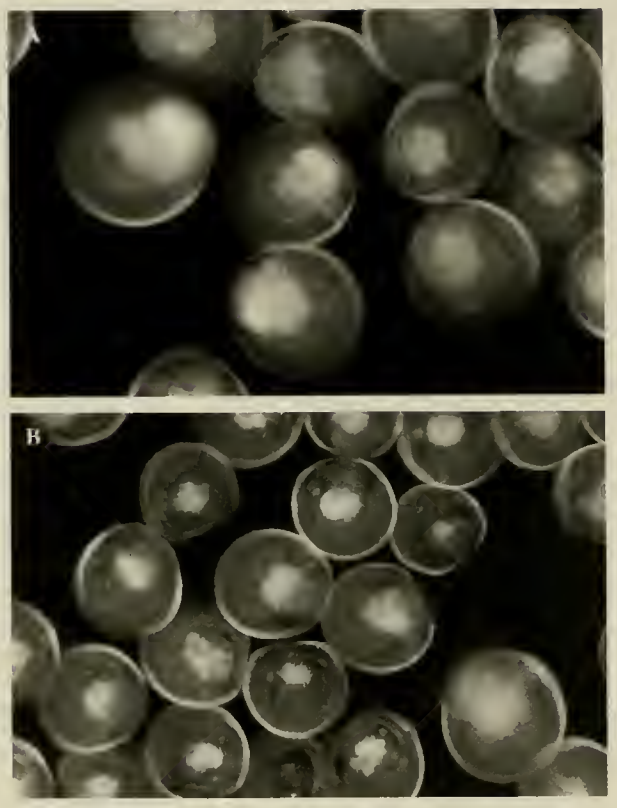

Figure. 2. Eight-day-old larvae of the Pacific oyster (*Crassostrea gigas*) viewed under epifluorescent light (excitation 355–425 nm, emission 525 nm) at ×400 magnification. Average larval shell length = 122 µm. Top: Larvae fed on riboflavin-containing lipid spray beads (50 beads/µL) for 1 hour, followed by a 2- hour period of feeding on T-ISO alone. Bottom: Larvae fed on *Isochrysis* sp. (T-ISO) alone for 2 hours.

Breakdown of SB and Uptake of Released Riboflavin by Adult Oysters

ANOVA of log-transformed riboflavin concentrations in oysters fed on riboflavin-SB were significantly greater (SNK; $P < 0.05$) than those of oysters either fed on seawater-filled SB or exposed to riboflavin dissolved in seawater (Table 1). The presence of significantly higher concentrations of riboflavin in the hemolymph, adductor muscle, and mantle of oysters fed on riboflavin-SB indicated that oysters were able to digest the lipid walls of SB and absorb released riboflavin. There were no significant differences in riboflavin concentrations in hemolymph sampled from either the heart or adductor muscle (ANOVA; $P > 0.05$).

Concentrations of riboflavin in the tissues of oysters exposed to dissolved riboflavin were not significantly (SNK; $P > 0.05$) different from those of oysters fed on seawater-filled SB, indicating a limited ability of adult oysters to take up dissolved riboflavin from seawater.

CONCLUSIONS

Feeding experiments indicated that both oyster larvae and adults were able to breakdown SB and release riboflavin. Free

TABLE 1.

Concentration of riboflavin in tissues of adult Pacific oysters exposed to either lipid spray beads (SB) containing 13% riboflavin at a concentration of 20 SB/μm, seawater-filled SB at a concentration of 20 SB/μL or dissolved riboflavin at the same concentration as that delivered by riboflavin-SB (1.15 mg/L).

Treatment	Stomach Contents (ng/mL)	Hemolymph		Mantle (ng/mg PCA-soluble protein)	Adductor muscle (ng/mg PCA-soluble protein)
		Heart (ng/mg protein)	Muscle (ng/mg protein)		
Seawater-filled SB	20 ± 4	47 ± 19	21 ± 10	198 ± 94	177 ± 115
Dissolved riboflavin	24 ± 4	84 ± 53	51 ± 32	112 ± 22	67 ± 20
Riboflavin-SB	7274 ± 1619	1844 ± 660	1165 ± 247	1633 ± 573	10636 ± 3808

Values are given as means (±1 SE, $n = 6$).

riboflavin was evident in the stomachs of larvae and elevated riboflavin concentrations were evident in the tissues of adult oysters after being fed on riboflavin-SB. Adult oysters exposed to concentrations of dissolved riboflavin, equivalent to those supplied by encapsulated riboflavin, did no show elevated tissue concentrations of riboflavin, indicating that uptake of dissolved riboflavin lost from SB was not a significant source for adult oysters.

About half of the riboflavin was lost during the preparation of SB, based on a comparison between the measured encapsulation efficiency of 13% and a maximum theoretical encapsulation efficiency of 25%. Further losses of riboflavin from SB occurred after suspending SB in seawater; for example, it can be estimated (based on Eq. 1) that 39% of encapsulated riboflavin would have been lost at the end of each 2-hour period of the adult feeding experiment.

In this study, retention of riboflavin by SB suspended in seawater for 24 h was only 27% compared with 85% reported by Buchal and Langdon (1998). This difference may have been attributable to higher encapsulation efficiencies of SB used in this study, because riboflavin-SB prepared by Buchal and Langdon (1998) had an encapsulation efficiency of 4.8% compared with an encapsulation efficiency of 13% for SB used in this study.

The effects of additions of riboflavin-SB on the growth and survival of oysters needs to be determined in future experiments. Because of the need to prepare SB with a high proportion (> 60%) of lipid wall material to ensure encapsulation of the core material, it is unlikely that SB will be useful in delivering bulk dietary ingredients, such as protein and carbohydrate, to oysters. However, SB may be useful in supplementing algal or artificial diets with water-soluble micronutrients, such as essential amino acids or water-soluble vitamins (Seguineau et al. 1996).

ACKNOWLEDGMENTS

This research was supported by a fellowship from the Organization for Economic Cooperation and Development (OECD), cooperative research program: Biological Resource Management for Sustainable Agricultural Systems. We also thank Jacques Panfili for his help in taking photographs of larvae fed on SB.

ABSTRACT A temperature-disease course model was developed to predict the effect of seasonal water temperature changes on disease progression of Dermo in field populations of *Crassostrea virginica*. A linear model was used to describe the relationship between weighted prevalence (disease intensity) and lagged cumulative temperature, where cumulative temperature was used as an estimate of cumulative harm. The model developed for Long Island Sound showed the strongest relationship between cumulative temperature and disease intensity when a lag time of 53 days was used. Point and interval estimates for the day(s) of the year when a mean weighted prevalence of 2 (Mackin Index) is expected at four sites in Long Island Sound are given. This model allows the grower/manager to predict Dermo intensity in shellfish beds if field water temperature patterns are known. Such information can be used to select oyster growout beds and determine optimal time to harvest.

KEY WORDS: *Perkinsus marinus*, Dermo, temperature-disease course model, Long Island Sound

INTRODUCTION

Perkinsus marinus (commonly known as "Dermo"), a protozoan pathogen of uncertain phylogenetic affinities (Siddall et al. 1995) is now well established in Long Island Sound (Brousseau et al. 1994, Brousseau 1996, Ford 1996, Brousseau et al. 1998) and has been reported as far north as the Damariscotta River in Maine. This pathogen is a major cause of oyster mortality in the Gulf of Mexico and Chesapeake Bay. Its introduction to Long Island Sound, the third largest producer of commercial oysters in the U.S., has prompted efforts to develop management strategies and husbandry protocols to help control the spread of this disease.

The influence of temperature on the activity of *Perkinsus marinus* is well documented. Temperature affects multiplication rates, virulence (Andrews 1988) and zoosporulation of the parasite (Chu and Greene 1989), and disease intensity in the host increases with increasing temperature (Chu and LaPeyre 1993). Temperature is also believed to be the most important factor affecting the geographic distribution and seasonal cycle of this pathogen (Andrews 1988, Andrews and Ray 1988, Crosby and Roberts 1990, Soniat and Gauthier 1989).

Modeling studies also point to the importance of temperature in the development and maintenance of *Perkinsus marinus* infections. Simulations have shown that the timing and duration of long-term climatic changes are important in determining levels of infection in diseased (coinfection by MSX and Dermo) oyster populations (Powell et al. 1992); whereas, the results of Hofmann et al. (1995) suggest that temperature is the primary factor regulating the parasite in the Gulf of Mexico.

Soniat and Kortright (1998) recently developed a model to estimate the time to a critical level of *Perkinsus marinus* in eastern oysters using a long-term dataset of temperature, salinity, and parasite infection level. Their model indicates that both temperature and salinity are important variables in predicting Dermo progression in areas such as the Terrebonne estuary of Louisiana, where fluctuations in salinity are high and salinity levels often fall below 10 ppt. In high-salinity, oyster-producing regions such as Long Island Sound; however, it is likely that water temperature is the more important factor in controlling parasite proliferation.

This paper reports the results of a modeling study aimed at predicting the effect of short-term (seasonal) temperature changes on disease progression of "Dermo" in oyster populations from New York and southern New England. The annual cycle of *Perkinsus marinus* infections in oysters from six locations in Connecticut, Massachusetts, and New York is presented, and a predictive temperature-disease course model developed for wild and commercial oyster beds in Long Island Sound is described. A discussion of the usefulness of this model to oyster aquaculturists is also presented.

MATERIALS AND METHODS

Data Collection

Oysters (*Crassostrea virginica*) were collected twice a month from six locations in Connecticut, New York, and Massachusetts from January to December 1997 (Figure 1). Most samples contained 25 oysters; a total of 3,786 animals were studied. Sampling locations, site descriptions, sample sizes, and ages (juvenile vs. adult) of oysters sampled are provided in Table 1. Tissue diagnosis of *Perkinsus marinus* was done by culture of rectal and mantle tissue in fluid thioglycollate medium, as described by Ray (1954). Infections were scored for intensity of disease by use of the measure originally described by Mackin (1962) as the weighted incidence and later renamed weighted prevalence (Ragone and Burreson 1994). On the Mackin Index, scores of 0.5–1.0 indicate light infections, scores of 2.0–3.0 indicate moderate infections and scores of 4.0–5.0 are considered heavy.

Temperatures (°C) were monitored at each site using an Optic Stowaway™ Temperature Logger (Onset Computer Corp.). At intertidal sites, the recorder was attached to a stake driven into the flat, and at subtidal locations, it was suspended over the shellfish bed along a buoy system anchored to the bottom. As a backup against loss or failure, temperatures were also taken by hand several times a month. Periodic salinity measurements were taken to

substantiate earlier reports that salinities at the study sites routinely run in the 20 to 30 ppt. range (Brousseau 1996, S. Ford pers. comm). They are shown in Table 2.

Mean Temperature Model

The mean temperature, T(x), for sampling day x can be modeled as a cyclic function

$$T(x) = \mu - \Delta \cos[c\ (x - x_{low})]$$

where μ is mean temperature for the year, Δ is one-half the range of mean temperatures (the amplitude), x_{low} is the day with the lowest mean temperature, and c is the constant needed to make the period equal to one year ($c = 2\pi/365.25$).

For x between the time of lowest mean temperature and highest

Cotuit, MA	7	26.5 ± 0.3	25.0–27.0

mean temperature, the cumulative temperature, CT(x), is the area under the temperature curve from time x_{low} to time x:

$$CT(x) = \mu\,(x - x_{low}) - \Delta \sin[c\,(x - x_{low})]/c.$$

Separate temperature models were developed for each site (Black Rock Harbor, n = 309; Cotuit, n = 93; Mystic River, n = 365; Oyster Bay, n = 146; Thames River, n = 365; Westport, n = 365). Weighted nonlinear least squares analysis was used to fit the parameters.

Temperature—Disease Course Prediction Model

A linear model was used to describe the relationship between weighted prevalence y and lagged cumulative temperature for sampling day x and site s:

$$y = a + b\,CT_s\,(x - lag).$$

In this formula, $CT_s\,(x - lag)$ is the area under the mean temperature curve for site s from the time of lowest mean temperature to time x minus the lag. Cumulative temperature is used as an estimate of cumulative harm; parasite proliferation is assumed to be a function of ambient water temperature patterns at each site.

Samples with sampling day on or after the mean low temperature day for the site formed the working set for the analyses. A total of 87 samples were used (Bridgeport, n = 23; Mystic River, n = 20; Thames River, n = 21; Westport, n = 23). The lag was chosen to maximize the correlation between weighted prevalence and lagged cumulative temperature. The slope and intercept were then estimated using linear least squares. The model with best overall fit was chosen. Bootstrap analysis using 1,000 resamples was used to estimate the sensitivity of the choice of lag time in the model (Efron and Tibshirani 1993).

Model Predictions

To make predictions, a weighted prevalence of 2.0 was selected as the parameter of interest since we considered it a critical stage in the progression of the disease. Andrews (1988) reported that some mortalities are likely to occur when the mean intensity for a population exceeds 1.0; however, severe mortalities (50–75%) are not expected until the wp reaches 3.0 (Ray and Chandler 1955, Mackin 1961, Mackin and Hopkins 1961). Site-specific temperature models were then used to obtain point estimates for the day with mean weighted prevalence of 2.0. A bootstrap analysis with 1000 resamples was used to construct 95% confidence intervals for the day with mean weighted prevalence of 2.0 at each site.

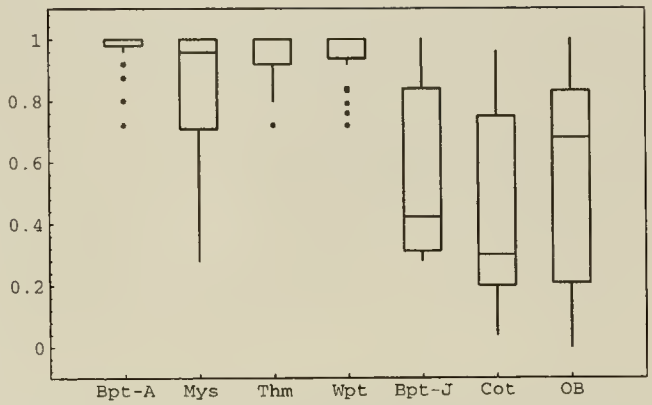

Figure 2. Side-by-side box plots of disease prevalence in juvenile and adult oysters. Adult populations in Bridgeport (n = 25 samples, median = 100% infected), Mystic River (n = 23 samples, median = 96% infected), Thames River (n = 23 samples, median = 100% infected), and Westport (n = 23 samples, median = 100% infected) and juvenile populations in Bridgeport (n = 10 samples, median = 42% infected), Cotuit (n = 24 samples, median = 30% infected), and Oyster Bay (n = 23 samples, median = 68% infected) are represented.

RESULTS

Descriptive Statistics

Disease prevalence in adult and juvenile oysters from all sites during 1997 is shown in Figure 2. Median values were between 96 and 100% for adult samples and between 30% and 68% for juvenile samples.

Distributions of weighted prevalences among sites are shown in Figure 3. The highest median weighted prevalence was found at the Saugatuck River site, followed by the Thames River and Black Rock Harbor sites. The median weighted prevalence was highest at sites where adult oysters were sampled (1.4–2.2); median weighted prevalence in juvenile oyster samples did not exceed 0.5. Distributions of proportions of oysters in all samples with intensity score of 2.0 or more on the Mackin scale is given in Figure 4. Median values for adult samples were between 32 and 60%; median values

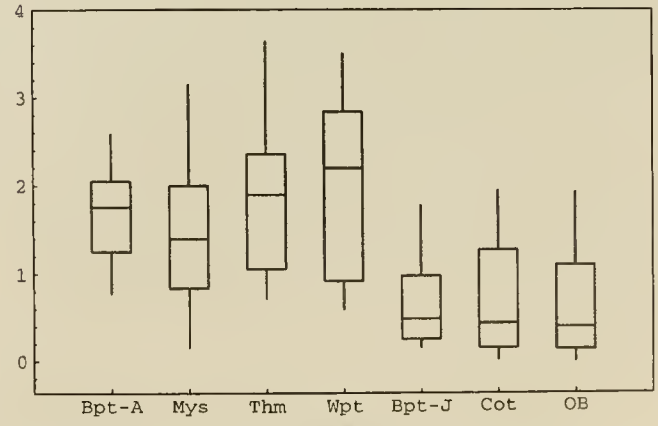

Figure 3. Side-by-side box plots of weighted prevalence in juvenile and adult oysters. Adult populations in Bridgeport (n = 25 samples, median = 1.76 wp), Mystic River (n = 23 samples, median = 1.40 wp), Thames River (n = 23 samples, median = 1.90 wp), and Westport (n = 25 samples, median = 2.20 wp) and juvenile populations in Bridgeport (n = 10 samples, median = 0.49 wp), Cotuit (n = 24 samples, median = 0.44 wp), and Oyster Bay (n = 23 samples, median = 0.40 wp) are represented.

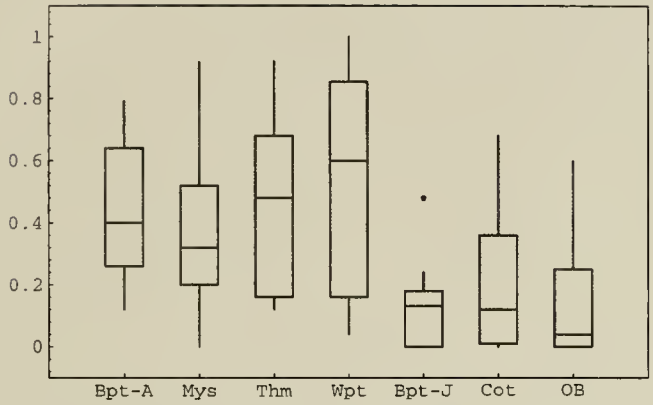

Figure 4. Side-by-side box plots of proportion with intensity score of 2.0 or more. Adult populations in Bridgeport (n = 25 samples, median = 40%), Mystic River (n = 23 samples, median = 32%), Thames River (n = 23 samples, median = 48%), and Westport (n = 25 samples, median = 60%) and juvenile populations in Bridgeport (n = 10 samples, median = 13%); Cotuit (n = 24 samples, median = 12%); and Oyster Bay (n = 23 samples, median = 4%) are represented.

for juvenile samples were between 4 and 13%. The largest proportions were observed at the Mystic River, Saugatuck River, and Thames River sites.

In adult oysters from Bridgeport, Thames River, Mystic River, Cotuit and Westport, weighted prevalence values increased dramatically during a 50-day period from the beginning of June to the middle of July. The proportion of individuals with infection intensities of 3.0 or higher also climbed during that time interval. In oysters from Oyster Bay, the shift from lower to higher weighted prevalences, and from a low to high proportion of moderate to severely diseased individuals also occurred over a 50-day period, but it happened later in the year (Figure 5). This result suggests a pattern of seasonal parasite proliferation for a population that begins in late spring or early summer and continues over a 7-week period, before reaching a plateau in mid- to late summer.

Temperature Models

Temperature model parameter estimates for each site are given in Table 3. Temperature patterns during 1997 were most similar at the Black Rock Harbor, Oyster Bay, Thames River and Westport sites, where mean maximum temperatures were between 21 and 23 °C. At Cotuit, on the other hand, mean temperatures peaked at 26 °C; whereas, in the Mystic River, mean temperatures reached a maximum of only 19 °C (Figure 6). The percentage of variation explained by the models ranged from 95 to 98%. The onset of seasonal proliferation of *Perkinsus marinus* at the study sites (Figure 5) coincides with approximate ambient water temperatures of 13 °C at the Mystic River, 16 °C at Bridgeport, Westport and the Thames River, and 20 °C at Cotuit and Oyster Bay (Figure 6).

Temperature—Disease Course Prediction Model

The prediction model with a lag time of 53 days gave the best over-all fit, explaining 45.1% of the variation in the data. The model equation

$$y = 0.94611 + 0.000899753\ CT_{x-53}$$

is based on 50 samples satisfying the condition that the sampling day minus 53 is between the mean low and mean high temperature days. Point and interval estimates for the day of the year with mean weighted prevalence of 2.0 are shown in Table 4.

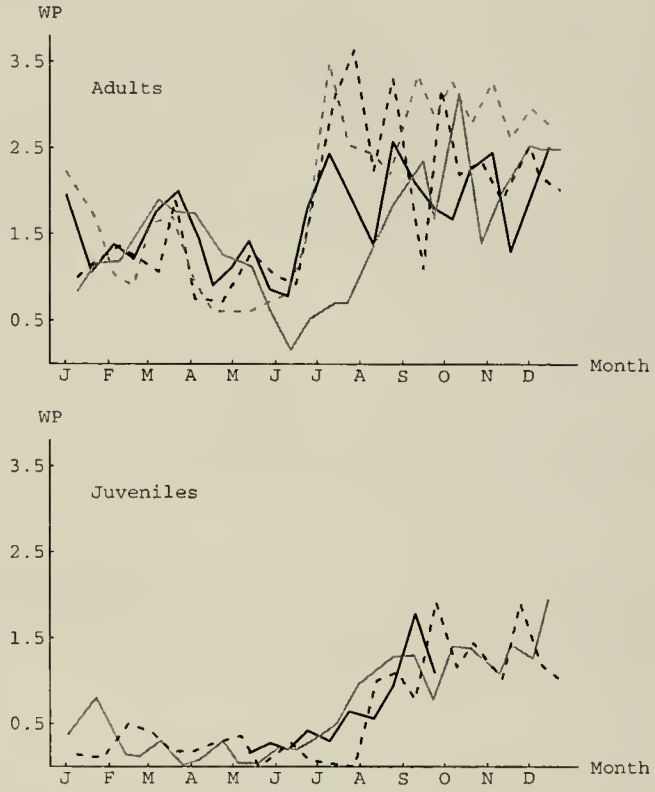

Figure 5. Graphs of weighted prevalence over time. Top plot: Bridgeport adults (n = 25 samples, solid black), Mystic River (n = 23 samples, solid gray), Thames River (n = 23 samples, dashed black), Westport (n = 25 samples, dashed gray). Bottom plot: Bridgeport juveniles (n = 10 samples, solid black), Cotuit (n = 24 samples, solid gray), Oyster Bay (n = 23 samples, dashed black).

For comparison, separate site-based models were developed and gave similar predictions.

DISCUSSION

Many of the characteristics of the Dermo epizootic in the northeast are similar to those described for epizootics in other areas. Disease prevalence is higher in adult oysters than in juveniles. Infection levels differ among size classes (ages); higher parasite burdens are found in adult oysters throughout the year. The lower infection intensities generally reported for juvenile oysters (Ray 1954) are believed to be the result of the relative growth rates of host and parasite (Mackin 1951, Hofmann et al. 1995). The plateau of high infection intensity seen in the northeast during the summer

TABLE 3.

Temperature model parameter estimates (μ: mean temperature; x_{low} = time of minimum average temperature; Δ = amplitude) for each study site.

Sampling Site	μ	x_{low}	Δ
Black Rock Harbor, Bridgeport, CT	12.19	35.16	10.59
Cotuit, MA	13.70	23.47	12.49
Mystic River, Stonington, CT	11.31	50.07	8.00
Oyster Bay, NY	11.40	40.14	11.67
Thames River, Waterford, CT	13.23	38.54	9.36
Saugatuck River, Westport, CT	11.33	38.68	10.49

has been reported for other infected populations as well (Crosby and Roberts 1990, Soniat 1985). The simulation study by Hofmann et al. (1995) has suggested that this buffering of infection intensity at levels of 3 to 4 on the Mackin scale may be attributable to two factors: (1) a decrease in parasite division rate at high parasite density; and (2) replacement of oysters that reach a lethal level of infection with less heavily infected oysters.

The northward spread of *Perkinsus marinus* into New England was not widely anticipated, because it had been viewed as a "warm-water" pathogen, which required minimal temperatures of 20 °C and extended periods of temperatures above 25 °C to establish an epizootic (Andrews 1988). Failure to predict the range expansion that has occurred may be attributable in part to lack of reliable water temperature data for oyster-growing areas. The most northerly site in this study, Cotuit, a shallow embayment on Cape Cod, experienced the highest mean water temperatures with temperatures consistently above 25 °C for over a month (Table 3; Figure 6), conditions similar to those reported for Delaware Bay (Ford 1996). The lowest mean water temperatures were recorded at Mystic, a deep-water site strongly affected by tidal exchange in and out of Long Island Sound. Site characteristics such as tidal exposure, water depth, tidal currents, and proximity to rivers or substantial freshwater inflow can be more important factors in determining the temperature characteristics of an area than its geographic location.

Infection levels in oyster populations began climbing when water temperatures reached 13–16 °C at the Bridgeport, Mystic River, Thames River, and Westport sites. This finding supports

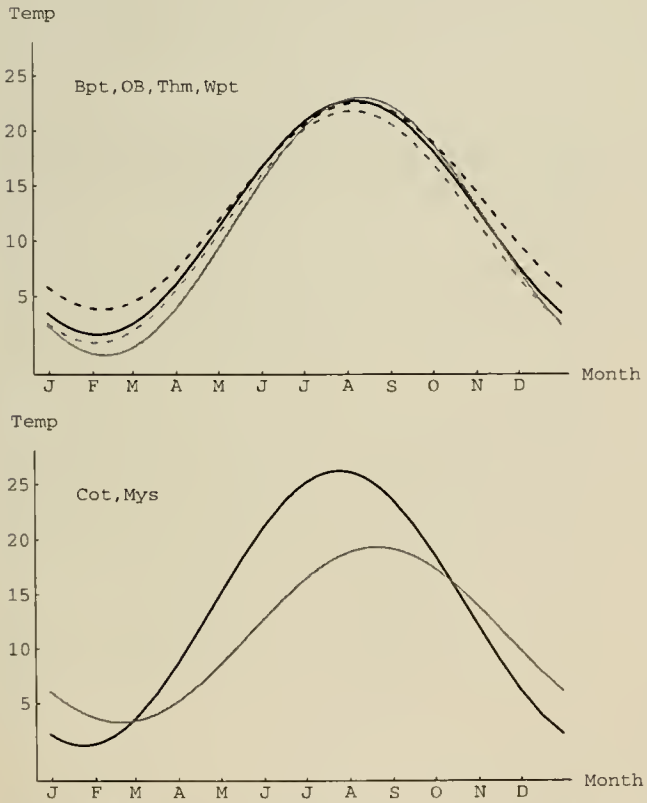

Figure 6. Mean temperature curves. Top plot: Bridgeport (maximum = 23 °C, solid black), Oyster Bay (maximum = 23 °C, solid gray), Thames River (maximum = 23 °C, dashed black), Westport (maximum = 22 °C, dashed gray). Bottom plot: Cotuit (maximum = 26 °C, solid black), Mystic River (maximum = 19 °C, solid gray).

TABLE 4.

Point and interval estimates for day of year with mean weighted prevalence of 2.0 determined for each study site.

Study Site	Day of Year	
	Point Estimate	Interval Estimate
Bridgeport	222	208, 237
Mystic River	237	221, 254
Thames River	215	200, 231
Westport	226	211, 241

earlier observations made for the Bridgeport population (Brousseau 1996). A later onset of parasite proliferation occurred among the juvenile oyster populations at Oyster Bay and Cotuit, when temperatures of 20 °C were reached, but the reason for the difference in timing is not known. Nonetheless, these results show a significantly different pattern of infection development from those reported in oysters from locations further south, where temperatures ≥20 °C are required for parasite proliferation (Andrews 1988). The reason for these observed differences in the temperature-time course of the disease are unknown, but possible hypotheses include: (1) the existence of a low temperature-adapted strain of the parasite (Bushek and Allen 1996, Dungan and Hamilton 1995) and/or (2) physiological differences in the immune systems of oysters from different geographic areas.

Soniat (1985) failed to find a correlation between water temperature and prevalence or intensity of *Perkinsus marinus*, but Crosby and Roberts (1990) found a statistically significant but weak correlation between water temperature and Dermo intensity. In a study that introduced lags into the relationship, Burreson and Calvo (1996) found significant correlation between water temperature and both prevalence and intensity of *Perkinsus marinus* in the Chesapeake Bay when lags of 2 to 4 months were used. The strongest relationship was with a 3-month lag; 46% of the variability in weighted prevalence and 39% of the variability in prevalence was explained.

The model developed for Long Island Sound showed the strongest relationship between cumulative temperature and *Perkinsus marinus* intensity when a lag time of 53 days was used. This result is similar to previous reports in the literature of significant correlations between temperature and parasite intensity when temperature was lagged by 60 days or more (Burreson and Ragone-Calvo 1996). It predicted that the oyster population from the Thames River would reach critical disease intensity levels (wp = 2) by late July/early August; whereas, similar intensity levels would not appear in the Mystic River until a month later. The eventual impact of the disease may depend on the time of the year when critical disease levels are attained. Very high oyster mortalities were experienced in the Thames River after mid-August 1997 (Janke pers. comm.) but no unusual mortalities were reported in the Mystic River during the year. The oyster mortality at the Thames River site may be attributable to high infection levels early in the season (Fig. 5) and higher mean temperatures during the year (Table 3). Any mortalities that may have occurred at the uncultivated sites (Bridgeport and Westport) went largely undocumented.

Water temperature is likely the most important single factor responsible for the establishment of *Perkinsus marinus* in the region of study, and although not controllable, knowledge of how the disease responds to differing environmental temperature patterns

can be helpful in managing oyster stocks in the face of disease pressure. Unlike most previous attempts to model the effects of environmental factors on the development and activity of *P. marinus* epizootics (Powell et al. 1992, Hofmann et al. 1995), this model has the advantage of being simple to use and having modest data requirements. It allows the grower to predict disease intensity in shellfish beds if field temperature patterns are known. The grower can then use this information in selecting oyster growout beds and determining optimal harvesting times for his product.

Admittedly, one drawback of using such a simple model for predicting parasite proliferation in the field is its failure to take into account additional factors that may affect local patterns of disease progression such as changing size frequency distributions within the population, yearly variations in food supply and annual changes in disease prevalence (Soniat et al. 1998). Also, this model was developed using only one year of data; it would benefit from additional tests over a longer time period to substantiate its general applicability. In spite of these shortcomings; however, the modeling approach presented here shows promise, and with further testing could prove to be a useful tool in industry efforts to minimize the impact of Dermo disease.

ACKNOWLEDGMENTS

We thank S. Ford and R. Smolowitz for providing unpublished data on Oyster Bay and Cotuit oysters. Our thanks also go to D. Relyea, F. M. Flower & Sons, and T. Janke, Ram Island Oyster Co. for providing oysters and valuable conversations during the course of this study. The following students: K. Cuniff, J. Guedes, C. Infantolino, C. Lakatos, G. LeCleir, R. Pinsonneault, and A. Takesy are also appreciated for their help with data collection. The final version of the manuscript benefited greatly from the comments of reviewers, E. Powell and T. Soniat. This research was supported by NRAC Grant No. 94-38500-0044.

ABSTRACT Growth rate, cell size, osmotic tolerance, and volume regulation were examined in cells of *Perkinsus marinus* cultured in media of osmolalities ranging from 168 to 737 mOsm (6.5–27.0 ppt). Cells cultured at the low osmolalities of 168 and 256 mOsm (6.5 and 9.7 ppt) began log phase growth 4 days postsubculture, whereas cells cultured at the higher osmolalities 341, 433, and 737 mOsm (12.7, 16.0, and 27.0 ppt) began log phase growth 2 days postsubculture. During log phase growth, cells from the higher osmolalities 341, 433, and 737 mOsm had shorter doubling times than cells from the lower osmolalities 168 and 256 mOsm. During both log and stationary phase growth, the mean cell diameter of cells cultured at 168 mOsm was significantly greater than cells cultured at 341 and 737 mOsm; the mean diameters of cells cultured at 341 and 737 mOsm did not differ significantly from each other. *P. marinus* cells cultured in various osmolalities were exposed to artificial seawater treatments of 56–672 mOsm (2.5–24.7 ppt). After the hypoosmotic treatment of 56 mOsm, cells that had been cultured in medium of low osmolality, 168 mOsm, showed only 41% mortality whereas the cells from the 341-, 433-, and 737-mOsm culture groups experienced 100% mortality. During the hyperosmotic shock, all of the groups exhibited mortalities of less than 10%. In *P. marinus* cells cultured in medium of 737 mOsm and then placed in a 50% dilution, cell diameter increased 13%, which was a volume increase of 44.5%, but cells returned to baseline size (size before osmotic shock) within 5 minutes. *P. marinus* cells cultured at low osmolalities can withstand both hypo- and hyperosmotic stress and use volume-regulatory mechanisms during hypoosmotic stress. Results suggest that transferring infected oysters to low salinity will result in strains of *P. marinus* acclimated to low salinity that will be able to withstand periodic events of extremely low salinity.

KEY WORDS: Osmotic tolerance, volume regulation, *Perkinsus marinus*

INTRODUCTION

Perkinsus marinus, a parasite of the eastern oyster, *Crassostrea virginica* (Gmelin), was first reported in the Gulf of Mexico (Mackin et al. 1950) but is now observed in *C. virginica* along the Atlantic west coast from Maine to Florida and in the Gulf of Mexico from Florida to Mexico (Andrews and Hewatt 1957, Mackin 1962, Burreson et al. 1994a). Since the 1950s and especially since 1986, *P. marinus* has been a major cause of mortality in the eastern oyster in the Chesapeake Bay (Burreson and Ragone Calvo 1996).

The eastern oyster, *C. virginica*, is an osmoconformer, but the osmotic tolerances of the parasites *Haplosporidium nelsoni* (MSX) and *P. marinus* living within the oyster are not clearly defined (Ford and Haskin 1988). Salinity is believed to be an important environmental factor that regulates the prevalence and intensity of *H. nelsoni* and *P. marinus*. These two common oyster parasites, however, appear to have differing tolerances to hypoosmotic conditions. Ford (1985) reported a reduced prevalence of *H. nelsoni* in oysters in salinities lower than 15 ppt. Ford and Haskin (1988) showed that some killing of *H. nelsoni* occurred at 15 ppt with maximum elimination at 9 ppt, suggesting that the pathogen is physiologically unable to tolerate low salinities. *P. marinus* tolerates salinities lower than 12 ppt, but the mechanisms that allow survival in low-salinity environments have not been clearly defined (Ragone and Burreson 1993, Burreson and Ragone Calvo 1996). Studies have shown that low salinity has a retarding effect on *P. marinus* development (Ray 1954, Mackin 1962, Soniat 1985, Burreson and Ragone Calvo 1996). In addition, it has been reported that infection intensity of *P. marinus* is positively correlated with temperature and salinity (Soniat 1985, Soniat and Gauthier 1989, Crosby and Roberts 1990, Burreson and Ragone Calvo 1996). An *in vivo* study of oysters infected with *P. marinus* determined the critical salinity range for pathogenicity to be between 9 and 12 ppt, and that *P. marinus* was less virulent below 9 ppt (Ragone and Burreson 1993). Also, the study reported that lower salinities (6 and 9 ppt) delayed disease development, whereas infections at higher salinities (12 and 20 ppt) increased in intensity and resulted in higher levels of oyster mortality.

Despite these findings, little is known about the osmotic tolerance of *P. marinus* when faced with hypo- and hyperosmotic stress. Studies with both free-living and parasitic protozoa have shown that many protozoa have the ability to adjust their cell volumes when faced with external osmotic changes (Kaneshiro et al. 1969, Da Silva and Roitman 1982, Geoffrion and Larochelle 1984, Ahmad and Hellebust 1986, André et al. 1988, Cronkite and Pierce 1989, Hellebust et al. 1989, Darling and Blum 1990, Darling et al. 1990). Similarly, *P. marinus* may also utilize physiological mechanisms to adjust to its changing osmotic environment. Only one previous study has been conducted on the osmotic tolerance of *P. marinus* in the absence of host influences (Burreson

et al. 1994b). This study reported that cells cultured at 22 ppt and placed in extreme low-salinity treatments of 0 and 3 ppt had higher than 90% mortality. As a continuation of this work, we investigated the osmotic tolerances and volume-regulatory abilities of *P. marinus* cells, which have been cultured in a range of osmotic conditions (168–737 mOsm or 6.5–27.0 ppt) and exposed to various osmotic treatments (56–672 mOsm or 2.5–24.7 ppt).

MATERIALS AND METHODS

In Vitro Cultures of P. marinus

Cultures of *P. marinus* were maintained in Jeronie La Peyre-Oyster Disease Research Program-1 (JL-ODRD-1) medium (La Peyre et al. 1993) (approximately 737 mOsm or 27.0 ppt) without bovine serum albumin (BSA) in a humid atmosphere at 28 °C in a 5.0% CO_2 incubator. Cells from the BSA-free acclimated cultures were transferred from 737-mOsm culture medium into 168, 256, 341, and 433 mOsm (approximately 6.5, 9.7, 12.7, and 16.0 ppt) media in a gradual procedure in which cells from 737 mOsm were placed into 433, 433 into 341 mOsm, etc., with the stepwise transfer occurring every 3 days. For culture maintenance, subculturing occurred every 2–4 wk. Cultures were seeded at a density of 5×10^6 cells per 5 mL of medium for all experiments, and during these experiments, subculturing occurred every 2 wk. Growth curves for the groups cultured at 168, 256, 341, 433, and 737 mOsm were determined by obtaining cell counts with a hemacytometer (Fisher Scientific) every day for 12 days starting the day after subculture to determine the time period of log phase growth. The growth rate study used cells approximately 20 generations (about 1 y) descending from the original cultures that were first acclimated to the different osmolalities. A generation is defined as one subculture. Cell size experiments used cells that were approximately 25–30 generations descended from the acclimated cultures. The osmotic tolerance experiments used cultures that were 7–10 generations descended from the original groups acclimated to the different osmolalities.

Culture Media

The cell culture medium used for the *P. marinus* cultures was the JL-ODRP-1 (La Peyre et al. 1993) without BSA. Media (100 mL) equivalent to 168, 256, 341, 433, and 737 mOsm were prepared before each subculture for the different culture groups following methods described by La Peyre et al. (1993). In addition to the reported constituents, the culture medium, depending on the desired osmolality (168, 256, 341, 433, and 737 mOsm), also included basal synthetic sea salts (0.3, 0.6, 0.9, 1.2, or 2.2 g), 0.2 g $NaHCO_3$, and KCl (0.0061, 0.0079, 0.0097, 0.0115, or 0.0177 g) dissolved in 91.5 mL tissue culture-grade water.

Cell Sizes of Cultured Cells

Cell diameters of the various *P. marinus* groups in both log and stationary growth phase were measured by using the NIH Image Analysis (Version 1.56) Macintosh computer program for particle size analysis and the MediaGrabber Macintosh program with RasterOps video digitizer board to capture live microscopic images from an inverted Zeiss light microscope (40× objective used in all of the cell size experiments). Cell measurement techniques with image analysis were based on methods described by Weeks and Richards (1993).

Baseline measurements were initially conducted to determine whether the groups cultured in media with osmolalities of 168, 341, and 737 mOsm varied in cell size. For log phase growth size distributions, cells cultured in 168-, 341-, and 737-mOsm media were harvested 6 days after subcultured and transferred to 15-mL microcentrifuge tubes. Each group of cells was declumped by repeatedly withdrawing the cells and passing them through a 3-mL syringe (25G 7/8-inch hypodermic needle). Cells were centrifuged at 800 *g* for 15 minutes, the medium decanted, and the cells resuspended in 10 mL of isotonic seawater. Seawater solutions (173, 365, and 740 mOsm or 6.7, 13.6, and 27.1 ppt) that were isotonic to the culture medium of each group consisted of 97.5 mL tissue culture-grade water, basal synthetic sea salts (0.45, 1.05, or 2.35 g), 0.2 g $NaHCO_3$, KCl (0.0061, 0.0097, or 0.0777 g), and 2.5 mL HEPES buffer (original concentration = 239.02 mg/mL). After resuspending the cell pellets in the isotonic artificial seawater solutions, cell solutions were stirred with a vortex mixer (Fisher Scientific), and a 10-μL sample was withdrawn from each group for cell counts using a hemacycometer. Volumes containing 1×10^5 cells from each group (168, 341, and 737 mOsm) were calculated, and these cell solutions were added to three different cell wells (three wells per group) in a cell well plate. From each well of each of the three groups, three to four images were captured. The number of cells per image ranged from approximately 40 to 70 cells. Clumped cells that could not be easily distinguished were excluded. This cell sizing protocol was also followed to measure cells cultured at 168, 341, and 737 mOsm in stationary phase growth (2 wk after subculture). Mean cell diameters were calculated for the culture groups from both log and stationary growth phase, and the relationship between culture medium osmolality and cell diameter was examined by a one-way analysis of variance. Significant differences between the groups cultured at the three different osmolalities were determined by using the Scheffé *post hoc* multiple comparison test.

Osmotic Tolerance

Buffered artificial seawater (ASW) treatment solutions of 56, 135, 222, 305, 386, and 672 mOsm (approximately 2.5, 5.3, 8.5, 11.4, 14.4, and 24.7 ppt, respectively) were prepared by dissolving synthetic basal salts (Sigma Chemical Co.) (0.0, 0.3, 0.6, 0.9, 1.2, or 2.2 g), 0.1176 g $NaHCO_3$, KCl (0.0014, 0.0044, 0.0061, 0.0078, 0.0097, or 0.0156 g), and 2.5 mL HEPES buffer (original concentration = 239.02 mg/mL) in 97.5 mL of tissue culture-grade water. After adding these constituents, the mixtures were adjusted to a pH of 7.5 and then filter sterilized. All of the treatment solutions, the BSA-free media for the culture groups, and the isotonic seawater solutions (used for cell size experiments) were analyzed on a vapor pressure osmometer (Wescor) to determine osmolalities. Cell density by hemacytometer and cell viability of the *P. marinus* cultures were assessed in each culture group (168, 256, 341, 433, and 737 mOsm). To determine cell viability, a 100-μL subsample was placed in a microcentrifuge tube and 10 μl of 0.05% neutral red stain added. After 10 min, two 10-μl aliquots were placed on the hemacytometer. Both live (stained) and dead (unstained) cells were counted for at least 200 cells. From each group, 2.0×10^6 cells were added to sterile 15-mL centrifuge tubes and the volumes raised to 7 mL with the treatment ASW at the osmolality equivalent to the medium osmolality. Then, 1 mL of each of these cell suspensions was centrifuged at 470 *g* for 5 min. The supernatant was decanted and the pellet resuspended in 1 mL of each of the treatment osmolalities (ASW) in a 24-well tissue culture plate. Thus, *P. marinus* cells cultured in media of 168, 256, 341, 433, and

737 mOsm were placed in ASW treatment osmolalities of 56, 135, 222, 305, 386, and 672 mOsm for 24 hours in 24-well microtiter plates at 28 °C in an incubator without CO_2. After the 24-hour incubation, 100 µL of neutral red was added and gently mixed with a pipette tip. Mortality was assessed by counting live and dead cells in two to three random grid fields with an inverted light microscope (Zeiss) and a 10 × 10-mm ocular micrometer grid. The experiment was repeated three times. Logistic regression analyses with SAS procedure Catmod were utilized to examine the response of the population (culture group) to the treatment osmolality and to calculate predicted mortalities (which describe the response of each population) with 95% confidence intervals for each of the culture groups at each treatment osmolality. A logistic regression model was chosen to represent the binary response of mortality (live *versus* dead). In addition, the actual live and dead cell counts were used for calculating percent mortalities and for an analysis that compares proportions from independent samples (Fleiss 1981).

Cell Size after Hypoosmotic Shock

Cell diameter changes following a hypoosmotic shock were measured with the MediaGrabber and NIH Image Analysis systems. Cells cultured in medium of 737 mOsm were harvested 2–3 wk after subculture, declumped with a 3-mL syringe (25G 7/8-inch hypodermic needle), and centrifuged at 800 *g* for 15 min. The medium was decanted, and isotonic seawater was added to obtain a volume of 10 mL. Cell density was determined with a hemacytometer, and a volume containing 1×10^5 cells was added to a cell well. A volume of 173 mOsm ASW was added to the well to result in a 50% dilution of the original seawater solution. Before adding this calculated volume of the hypoosmotic shock solution, an image was captured to represent time 0. Ten to twenty seconds after the 50% dilution, a second image was captured as time 1. Images were then captured at 1, 3, 5, 7, 10, 12, 15, 20, 30, 45, and 60 min after dilution. The same cells from the same plane were eaptured as images, and thus, the same population experiencing the shock was represented. These images were analyzed with the NIH Image Analysis system to determine cell diameters at each time interval. The experiment was repeated five times. The first experiment used cells 19 days postsubculture. The second experiment used cells from a different culture 18 days postsubculture and included time points of 0 and 10–20 sec, and 1, 3, 5, 10, 15, 20, and 30 min. The third, fourth, and fifth experiments used cells 20 days postsubculture and were performed consecutively on the same day with cells from the same flask. Experiments 3, 4, and 5 included images captured at 10–20 sec and 1, 3, 5, 10, 15, 20, and 30 min. Cell viability was assessed with the vital stain neutral red before the shock and 30 min after adding the shock solution. The control experiment used cells 21 days postsubculture and followed the protocol described above without adding the shock solution; images were obtained at 0, 1, 3, 5, 10, 15, 20, and 30 min. Cell sizes after hypoosmotic shock were analyzed with the nonparametrie Kruskall-Wallis test to first examine the effect of each experiment. To separate out the significant effect of each experiment but still look at the results of all trials together to examine the overall effect of the treatment osmolality on cell size, a mean center standardization was used by subtracting the mean cell diameter (total mean diameter for all time points within each experiment) from each data point. A second Kruskall-Wallis test was run on the standardized data to examine whether each experiment continued to have a significant effect on cell diameter. The effect of the experiment was no longer significant, and the experiments were pooled. A third Kruskall-Wallis test was used to determine whether time had a significant effect on cell diameter. Lastly, the Tukey-Kramer multiple comparison *post hoc* analysis was implemented to determine at which time points the mean cell diameters were significantly different from each other. An unpaired *t*-test was used to determine whether there was a significant difference between the standardized control diameters and the standardized replicate diameters (experiments pooled) both before the shock and 1 min after the shock.

RESULTS

Growth Rate

The results of the growth rate study indicated that log phase growth began approximately 2 days postsubculture for *P. marinus* cells cultured in 341, 433, and 737 mOsm (12.7, 16.0, and 27.0 ppt) media. Cultures from the 168 and 256 mOsm (6.5 and 9.7 ppt) media began log phase growth approximately 4 days postsubculture (Fig. 1). The groups cultured at the higher osmolalities of 341, 433, and 737 mOsm had shorter doubling times compared with the groups cultured at the low osmolalities of 168 and 256 mOsm. For the 168-mOsm cells, 35.2 h were required for one doubling and 35.7 h for the 256-mOsm cells. For the higher osmolality cells from 341, 433, and 737 mOsm, one doubling required 22.8, 25.9, and 24.4 h, respectively.

Cell Sizes of Cultured Cells

During log phase growth, the mean diameters (± standard error) of *P. marinus* cells cultured in media of 168, 341, and 737 mOsm were 11.8 (±0.191), 9.6 (±0.108), and 9.2 (±0.106) µm, respectively. The effect of culture medium osmolality on cell diameter

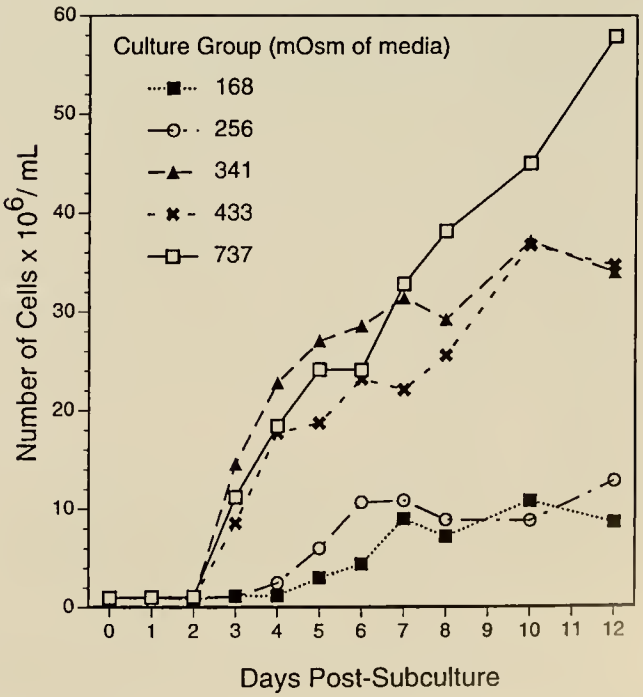

Figure 1. Growth curve of *P. marinus* cells cultured in media of 168, 256, 341, 433, and 737 mOsm (6.5, 9.7, 12.7, 16.0, and 27.0 ppt).

was statistically significant ($P = 0.0001$). Cells cultured at 168 mOsm were significantly larger than cells at either 341 ($P < 0.0001$) or 737 mOsm ($P < 0.0001$). The differences in diameter between cells at 341 and 737 mOsm were not significant ($P = 0.1565$). The mean diameters of stationary phase *P. marinus* cells cultured at 168, 341, and 737 mOsm were 8.4 (±0.165), 4.7 (±0.070), and 5.1 (±0.093) μm, respectively. As observed with cells from log phase growth, the effect of culture medium osmolality on cell size was statistically significant ($P < 0.0001$). Cells cultured at 168 mOsm were significantly larger than cells at either 341 ($P < 0.0001$) or 737 mOsm ($P < 0.0001$), whereas the difference in cell diameter between the 341- and 737-mOsm groups was only significant at the 5% level of significance ($P = 0.021$).

Osmotic Tolerance

Before osmotic shock, the mean viabilities of the *P. marinus* cells cultured at 168, 256, 341, 433, and 737 mOsm were 88.2%, 96.2%, 99.1%, 99.3%, and 98.8%, respectively. After hypoosmotic treatments, the percent mortality was lower in groups that were cultured in low-osmolality media than in groups from higher osmolalities (Fig. 2). For example, in the extreme hypoosmotic shock of 56 mOsm (2.5 ppt), mortality was 41% in cells cultured at an osmolality of 168 mOsm but was 100% in cells that were cultured at 737 mOsm. Conversely, in the hyperosmotic shock of 672 mOsm (24.7 ppt), groups that had been cultured at low osmolalities as well as high osmolalities all experienced mortalities of less than 10% (Fig. 2). A logistic regression analysis showed that a significant relationship existed between treatment osmolality as a function of mortality ($P < 0.001$). A comparison of proportions from independent samples test showed that the mortality response of the 168-mOsm group was significantly different ($P < 0.001$) from the mortality observed for the 737-mOsm culture group at the 56-mOsm treatment. Predicted mortalities determined from a logistic regression analysis indicated that in low-osmolality treatments, groups cultured at 168 and 256 mOsm have lower mortalities than the groups that had been cultured at 341, 433, and 737 mOsm.

Cell Size after Hypoosmotic Shock

Cell viability was not affected by the 50% dilution; the results of a viability test indicated a 99% viability before the dilution (time 0) and 97% viability 30 min after the dilution. From the first nonparametric analysis, it was difficult to examine the effect of osmolality on cell size because of variability between experiments and variability between experimental conditions. After implementing a mean center standardization, however, nonparametric analysis indicated that each experiment did not have a significant effect on cell diameter ($P = 0.8976$). Therefore, the results from each experiment could then be pooled. The overall response to the 50% hypoosmotic shock was an initial swelling followed by a return to baseline size (Fig. 3). When placed in the 50% dilution treatment, *P. marinus* cells that were cultured at 737 mOsm experienced an initial swelling between 0 and 30 sec after hypoosmotic shock. Cells swelled and returned to baseline size within about 5 min. The mean diameter change during swelling was 0.7 μm. The initial mean cell diameter was 5.7 μm, and thus, the percent diameter increase during initial swelling was approximately 13%, which was a 44.5% change in cell volume. The nonparametric analysis on the pooled, standardized data showed that time had a significant effect on cell diameter, with a tied P-value of <0.0001. The *post hoc* multiple comparison analysis with a $P < 0.05$ level of significance indicated that significant differences existed between the following time points: 0 and <30 sec, <30 sec and 5 min, <30 sec and 15 min, <30 sec and 20 min, and <30 sec and 30 min. The unpaired t-test showed no significant difference between the mean diameters of the control group and the experimental groups (all experiments pooled) at time 0 ($P = 0.2931$), but there was a significant difference at a significance level of $P < 0.05$ between the control group and the experimental groups 1 min after the shock ($P = 0.0022$).

DISCUSSION

Continuous cultures of *P. marinus* can be maintained in low-osmolality environments (as low as 168 mOsm or 6.5 ppt). Fur-

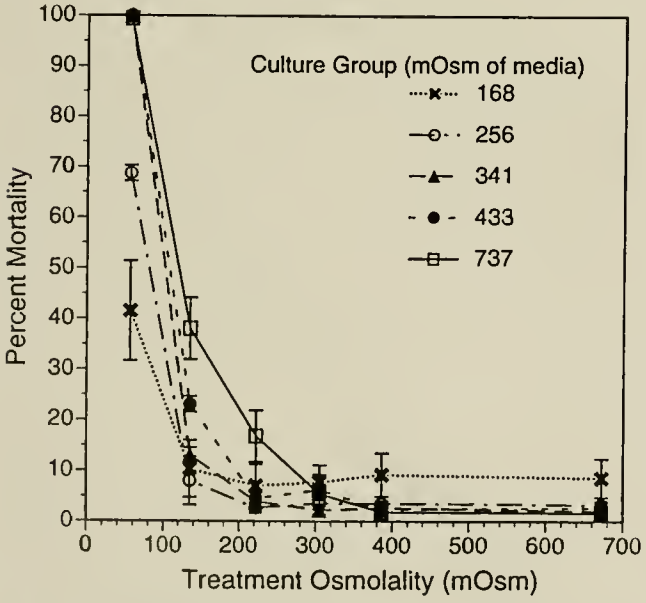

Figure 2. Percent mortality of *P. marinus* cells cultured in media of 168, 256, 341, 433, and 737 mOsm (6.5, 9.7, 12.7, 16.0, and 27.0 ppt) and placed in treatment osmolalities of 56, 135, 222, 305, 386, and 672 mOsm (2.5, 5.3, 8.5, 11.4, 14.4, and 24.7 ppt) for 24 h. Error bars = standard error.

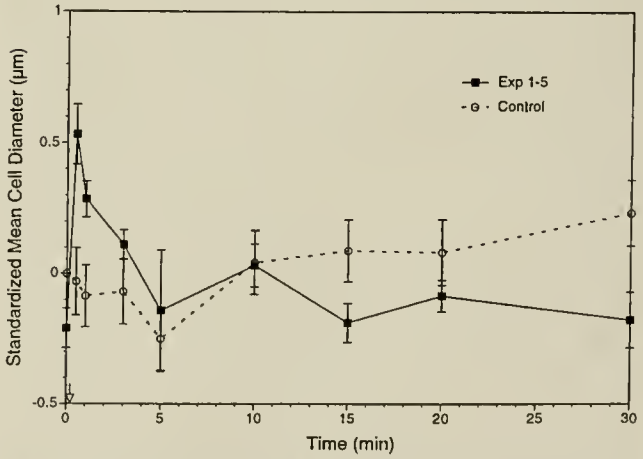

Figure 3. Standardized mean cell diameter (μm) of *P. marinus* cells cultured at 737 mOsm (27.0 ppt) and placed in 50% hypoosmotic shock (arrow) with experiments 1–5 pooled and the control experiment. Arrow indicates actual time of shock; time represents time after shock. Error bars = standard error.

thermore, cells maintained in osmolalities ranging from 168 to 737 mOsm (6.5–27.0 ppt) are tolerant of hypo- and hyperosmotic conditions in the treatment range of 222–672 mOsm (8.5–24.7 ppt). Cells cultured at low osmolalities can also withstand extreme low osmolalities such as 56 mOsm (2.5 ppt) for at least 24 hours. Thus, these experiments have shown that cultured cells of *P. marinus* can survive both hypo- and hyperosmotic stress. During hypoosmotic stress, cells increased in diameter, followed quickly by a return to baseline size (size before osmotic shock), which indicates a volume-regulatory response. This response helps explain why *P. marinus* continues to persist in the Chesapeake Bay despite periods of low salinity that occur during times of high rainfall and runoff into the tributaries.

The growth rate study showed that *P. marinus* cells that were cultured at osmolalities of 341, 433, and 737 mOsm (12.7, 16.0, and 27.0 ppt) reached log phase growth before cells cultured at lower osmolalities of 168 and 256 mOsm (6.5 and 9.7 ppt). In addition, cells from higher osmolalities had greater rates of multiplication (shorter doubling time) during log phase than cells cultured in low osmolalities. These results correspond to a study with trypanosome cultures that showed that media of high osmolality supported greater multiplication rates than low-osmolality media (Da Silva and Roitman 1982).

The osmotic tolerance study indicated that *P. marinus* cells cultured at low osmolalities experienced reduced mortality when placed in extreme hypoosmotic conditions when compared with the groups cultured at higher osmolalities. Because the cells were already acclimated to the stress of a low-osmolality environment, they were able to withstand an extreme low osmolality of 56 mOsm better than cells cultured at much higher osmolalities. Approximately 60% of the 168-mOsm cultured cells survived the extreme low osmolality of 56 mOsm for at least 24 hours. In this study, all of the culture groups had low mortalities (<10%) after hyperosmotic stress. Consequently, *P. marinus* was more tolerant of hyper- than hypoosmotic shock.

This research showed that the stressor did not seem to be the magnitude of the shock, but instead the type of shock (hypo- or hyperosmotic) and the actual osmolality of the challenge treatment. For example, the 737-mOsm cells placed into 222-mOsm treatment (a difference of 515 mOsm) had much higher mortality than cells from 168-mOsm placed into 672-mOsm treatment (a difference of 504 mOsm). Although the magnitude of the shock was about the same, the hypoosmotic rather than the hyperosmotic environment was more stressful, as indicated by higher mortality levels. In addition to the type of stress, the actual osmolality of the stress affected the level of mortality. For instance, cells acclimated to 737 mOsm and placed into 386-mOsm treatment (a difference of 351 mOsm) had much lower mortality (<10%) than cells from 433 mOsm placed into 56-mOsm treatment (a difference of 377 mOsm), which resulted in 100% mortality. Although the magnitude of both of the hypoosmotic shocks was similar, mortality was higher in the treatment with the lowest absolute osmolality, indicating the cells may have a threshold osmolality level needed for survival.

The results from the osmotic tolerance experiment differ from the study by Burreson et al. (1994b), which reported much higher mortality levels in cells acclimated to 737 mOsm and placed in the same hypoosmotic treatments. The study by Burreson et al. (1994b) showed greater than 60% mortality for cells acclimated to 737 mOsm and placed in treatments of 136 mOsm and 213 mOsm, whereas this study reports 15–40% mortality in the same low-osmotic treatments. One difference is that Burreson et al. (1994b) used *P. marinus* cells cultured in medium with BSA (known as JL-ODRP-1 media), whereas this study used cells cultured in BSA-free medium. However, comparative experiments with cells acclimated to either medium with BSA or BSA-free medium showed no significant difference between the effects of the two types of media on osmotic tolerance. Other factors that may have contributed to the differences in mortality between this experiment and the previous one include reported differences in experimental design such as the age of the cells (numbers of subcultures since isolation and initiation), growth phase of the cells, and type of incubator used (CO_2 or without CO_2). For example, the cells in the previous study were transferred to an incubator without CO_2 for 1 week before use, whereas cells in our experiment were in an environment without CO_2 for only 1 day. The prolonged exposure to an environment without CO_2 may have stressed the cells in the previous study, making them more susceptible to mortality after osmotic shock. Growth rates are reduced in cultures that have been transferred to an incubator without CO_2 when compared with cultures maintained in a 5.0% CO_2 incubator (La Peyre, personal observation).

Cells cultured at the low osmolality of 168 mOsm were significantly larger than cells cultured at the high osmolalities of 341 and 737 mOsm during both log and stationary growth phases. The cells cultured at the high osmolalities of 341 and 737 mOsm, however, were not significantly different from each other in size. The difference in cell size may be due to increased water content required to match the low osmolality of the dilute external medium. A study with red coelomocytes of the euryhaline polychaete *Glycera dibranchiata* showed cells acclimated to a lower osmolality had a higher "body-wall-tissue water content" and greater cellular volume than cells acclimated to a higher osmolality (Costa et al. 1980). An experiment with the amoeba *Acanthamoeba castellanii* indicated that the amount of intracellular water increased when cells were placed in a severe hypoosmotic shock (Geoffrion and Larochelle 1984). Similarly, the gradual acclimation of the *P. marinus* cells from high- to low-osmolality media when developing low-osmolality cultures may have caused an increase in size as water initially diffused into the cells, and the cells cultured in the low osmolality may not have been able to completely return to baseline size during volume regulation because of the stress of the prolonged hypoosmotic environment. Cells must maintain certain levels of metabolites to survive the stress of a low-osmolality environment. These levels of solutes attract water molecules because of simple diffusion, and therefore, an increased intracellular water content results. Studies on the erythrocytes of the bivalve *Noetia ponderosa* (Amende and Pierce 1980, Smith and Pierce 1987) and a report on the euryhaline ciliate *Paramecium calkinsi* (Cronkite and Pierce 1989) indicated that cells may not always completely return to baseline (size before osmotic shock) after volume regulation.

Alternatively, the difference in cell size of the groups cultured at low *versus* high osmolalities may be due to a difference in life stages of the groups that were measured. Cells of *P. marinus* divide by schizogony with a cell increasing in size, acquiring a vacuole, and then releasing several daughter cells (La Peyre and Faisal 1997). This process could have been occurring with some of the cells from the low-osmolality cultures during the cell-size experiment, as both small cells and large cells with smaller cells inside them were observed, whereas the groups measured at higher osmolalities mainly consisted of small cells. Thus, because the

low- and high-osmolality groups had different growth rates, they may not have been at the same growth stage when their cell diameters were measured, which could account for the differences in size between the groups. The cells from higher osmolalities were not observed as a large parent cell dividing into several smaller cells, but instead, one cell often appeared to divide into two (data not shown). *P. marinus* cells with high growth rates appear to divide as one small cell dividing into two cells (La Peyre 1996). The cells at the low osmolality, however, may be larger in size even before schizogony because of an increased internal water content. Further studies examining the relationship between medium osmolality, *P. marinus* growth stage, and cell size would be useful in understanding the role of osmolality in *P. marinus* growth and survival.

During the short-term hypoosmotic stress experiment in this study, *P. marinus* cells followed a typical cell volume response that is observed in other organisms by experiencing an initial swelling and then shrinkage back toward baseline (Costa et al. 1980, Smith and Pierce 1987, Cronkite and Pierce 1989, Darling et al. 1990). The results indicate that *P. marinus* cells do not resist swelling during sudden or extreme external osmolality changes. The size at the maximum swell was significantly different from the initial baseline and the acclimated sizes. The erythrocytes of the clam *N. ponderosa* exhibited a similar pattern when cells acclimated to 935 mOsm were placed in a hypoosmotic shock of 560 mOsm; the cells swelled, thereby increasing their volume by 50% within 5 min followed by a gradual return toward baseline (Smith and Pierce 1987). Because the cells in this study did swell and return to baseline size, the results suggest that *P. marinus* regulates the intracellular osmotic concentration to regulate cell volume during changing external osmolalities. The results reported here along with other studies by our laboratory (data not shown) and by Paynter et al. (1997) on intracellular osmolytes (i.e., free amino acids) used by *P. marinus* indicate that *P. marinus* cells utilize volume-regulatory mechanisms to compensate for osmotic changes in the external medium. These mechanisms enabled cells in this study to survive a 50% dilution of the external medium. But to better describe the specific volume-regulatory mechanisms used by *P. marinus*, current studies are focusing on measuring the levels of intracellular inorganic ions and organic molecules before, during, and after osmotic shock to determine their role in volume regulation.

The results of these experiments help explain why *P. marinus* continues to persist in the upper portions of the Chesapeake Bay tributaries despite periods of low salinities. Periodic increases in stream flow causing lowered salinities have not greatly affected the abundance of *P. marinus* in Chesapeake Bay tributaries (Burreson and Ragone Calvo 1994, Ragone Calvo and Burreson 1995). The fact that low salinities have not eradicated the pathogen from these areas may be explained by the results in this osmotic tolerance study that indicate *P. marinus* can use volume-regulatory mechanisms to adapt to changing external osmolality and become acclimated to extreme low osmotic conditions. Transferring infected oysters to low salinities may exacerbate the P. marinus problem by allowing acclimation of the parasites to lower salinities, thereby making them more tolerant of extremely low salinities. As a result, strains of *P. marinus* that are tolerant of a wide range of fluctuating salinities, including extremely low-salinity environments, may develop.

ABSTRACT All previous attempts to produce viable tetraploid pearl oyster (*Pinctada martensii* Dunker) by inhibiting the first polar body and the first mitosis have failed. This study aims to test the possibility of producing viable tetraploids by the intentional process of crossing triploid females and diploid males following the inhibition of the first polar body. When 0.5mg/L CB was applied to inhibit the release of the first polar body, about 16.69% of embryos developed as tetraploids, the majority of embryos were aneuploids (65.48%); about 82% embryos developed as aneuploids in the control group (TD1), but no tetraploid embryos were found. Ploidy of embryos in the TD1 group mainly fell between 2n and 3n, but ranged from 2n to 5n in the TDCB group. During rearing period, larvae died heavily. At Day 51 post-fertilization, 2125 spat were harvested, averaging 0.033% of D-larvae cultured. Chromosome analysis revealed that 115 one-year-old pearl oysters consisted of 28.70% diploids (n = 33), 40.87% triploids (n = 47), 1.74% tetraploids (n = 2) and 28.70% aneuploids (n = 33) with 29, 30, 40, 41, and 43 chromosomes. Comparison of growth showed that aneuploids was not significantly different from diploids in both shell length and body weight ($P > 0.1$), but significantly smaller than triploids ($P < 0.05$). This study demonstrated that the production of viable tetraploid pearl oysters with eggs from triploids is possible, and certain levels of aneuploidy can be tolerated in this species.

KEY WORDS: Tetraploid, aneuploid, triploid, *Pinctada martensii* (D.)

INTRODUCTION

Artificial triploid pearl oysters, *Pinctada martensii* (D.), have been successfully obtained (Jiang et al. 1987). Because of their reduced gonadal development, triploid pearl oysters grow faster than diploids (Jiang et al. 1993), and pearls cultured in triploids are significantly bigger than pearls from diploids in pearl size, weight, and pearl layer (Lin & Jiang 1993). On the other hand, the mortality of triploids isn't different from that of diploids during the adult stage (Lin et al. 1996). All of which suggest a promising future for pearl culture by using triploid pearl oysters. Now pilot-scale testing of pearl culturing in triploids is being conducted in China. However, the method of inducing triploids by inhibiting polar bodies rarely produces 100% triploids, and treatment of induction may have deleterious effects on the survival and growth of induced triploids. If crossing tetraploids and diploids could produce all-triploids as expected, the use of tetraploids may eliminat these problems. Tetraploid is commonly induced by inhibiting the first polar body, the first mitosis division or cell fusion. However, most of previous attempts to produce viable tetraploids in several species have failed (Stephens & Downing 1988; Diter & Dufy 1990; Guo et al. 1994; Jiang et al. 1998), which has eluded researchers leading to doubt that tetraploids were inviable in shellfish. Tetraploid embryos of pearl oyster were produced with several methods, including inhibition of the first polar body, the first cleavage division with cytochalasin B (CB) or pressure, and cell fusion with PEG, but none lived to adult age (Jiang et al. 1998).

Although many attempts to induce viable tetraploids in mollusks have failed, there are a few reports of success. For example, Scarpa et al (1993) produced tetraploid mussel (*Mytilus galloprovincialis*) as an incidental product by inhibiting both the first and second polar bodies with CB treatment. Out of 29 mussels sampled at 82 days after fertilization, 5 were tetraploids (17%). Tetraploid Manila clams, *Tapes philippinarum* (Adams and Reeve), were found in offspring produced by blocking the first polar body to induce triploids (Allen et al. 1994). Guo and Allen (1994a) reported that 67% of tetraploid juveniles produced by the inhibition of the first polar body of eggs from triploid Pacific oysters (*Crassostrea gigas* Thunberg), and all-triploid Pacific oysters have been produced by mating tetraploids and diploids (Guo et al. 1996). These reports renew interests in tetraploid induction in shellfish.

This study aims to induce tetraploidy with pearl oysters by crossing triploid females and normal diploid males following the inhibition of the first polar body, and look into the possibility of this intentional process to induce tetraploid pearl oysters.

MATERIALS AND METHODS

Triploid pearl oysters, *Pinctada martensii* (D.), used in this study were produced from 2n × 2n crosses by inhibiting the first polar body with CB treatment in 1996. Ploidy was confirmed by chromosome count prior to spawning. Gametes were obtained by dissecting gonads, and were passed through a 100 μm screen to remove the large tissue debris. Fertilization was conducted at 24–25 °C. Eggs from triploid females (about 7 cm in shell length and 2.5 cm in shell width) were fertilized with sperm from normal diploid males in 0.6‰ ammonia-seawater and treated with 0.5 mg/L CB to block the release of polar body 1 (as TDCB groups). CB treatment started at 6 min after fertilization and lasted 15 min After the treatment, eggs were rinsed with 0.1% DMSO in seawater and cultured at a density of about 1/mL in filtered seawater. The remains of feed and dead larvae were removed at regular intervals to maintain water quality. The resulting spat were cultured in the sea. The first treated group (TDCB1) had one female parent; the other three groups had two triploid females respectively. The group receiving no CB treatment is as the control (TD), only the first group had a control (TD1). All groups shared one diploid male. The experiments were conducted on April. 23, 1998.

To examine the ploidy of embryos, samples of developing zygotes of 2-cell stage were taken, and treated with 0.05% colchicine

TABLE 1.

The ploidy of embryonic cells in the treated groups and the control.

Group	Diploid (%)	Triploid (%)	Tetraploid (%)	Aneuploid (%)
TDCB1	15.89	11.21	20.56	52.34
TD1	12.00	6.00	0.00	82.00
TDCB2	13.73	8.82	22.55	54.90
TDCB3	5.83	5.85	11.65	76.69
TDCB4	5.00	5.00	12.00	78.00

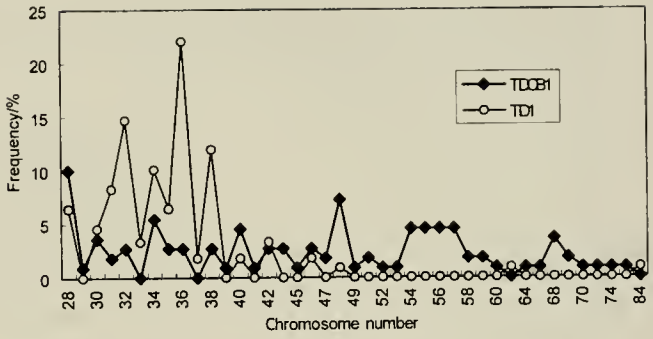

Figure 1. The distribution of chromosome number of embryonic cells in TDCB1 and TD1.

for 15 min, then fixed with Carnoy's solution (1:3 glacial acetic acid and absolute methanol). Fixatives were changed twice. Chromosomes were observed by acetic orcein stain. Briefly, drops of fixed samples were spread on a slide, stained with 1–2 drops of orcein stain (2% orcein in 50% acetic acid), and after 15–30 sec, covered with a cover glass and pressed gently. Slides were examined with a LEICA DMLS microscope; photographs were taken with black-and-white film with speed set at 100 ASA. Ploidy of embryos were determined according to $2n = 28 \pm 2$, $3n = 42 \pm 2$, $4n = 56 \pm 2$, others as aneuploids (normal diploid pearl oyster has 28 chromosomes). About 100 embryonic cells with good metaphases were counted for chromosome analysis in each group.

When pearl oysters reached 4 to 6 cm in shell length (on June 6, 1999), 230 pearl oysters were sampled. Each was numbered and measured for shell length (SL) and whole body weight (BW); a piece of gill was removed for chromosomal analysis. Gill tissues were treated with 0.05% colchicine in 50% seawater for 1h, then treated with 25% seawater (1 part seawater/ 3 parts distilled water) for 30 min, and fixed in a freshly prepared Carnoy's solution with three changes of 20 min duration. The tissue was stored overnight in fixatives in 4 °C. The next day the fixative was replaced by 50% acetic acid, gill tissue was treated for 10–30 min, then 2–3 drops of the resulting cell suspension were dropped onto a warmed slide (40–50 °C) and dried. Slides were stained with 10% Giemsa (pH6.8) for 40–60 min. Ploidy was determined by examining no less than five chromosome metaphases with the same chromosome numbers from gill cells. Individuals with 28, 42, and 56 chromosomes were classified as diploid, triploid and tetraploid respectively; any derivation from the euploid chromosome numbers was classified as aneuploid. Growth comparison between aneuploid and ploypoid was conducted by Student's *t*-test.

RESULTS

The female parent used in TDCB1 had approximately 61.92 million eggs, almost equal to normal diploids of the same size. The number of eggs obtained from seven triploid females in this study varied between 2.07 and 61.92 million. The average diameter of eggs from triploids was 57 μm, 14% larger than eggs from diploids (50 μm), which corresponded to about 50% increase in cell volume.

Chromosome examination showed that the ploidy level differed greatly among groups (Table 1). On average, there were about 16.69 ± 5.68% tetraploid embryos in the treated groups, while most of embryos were aneuploids, averaging 65.48 ± 13.75%. The percentage of aneuploids (82.00%) in TD1 was higher than that of TDCB1 (52.34%), but the percentage of polyploid (18.00%) was significantly lower than that of TDCB1 (47.66%), no tetraploids were found in the control. The distribution of chromosome numbers among embryos in TD1 and TDCB1 is showed in Figure 1. Ploidy of embryos in TD1 mainly fell between 2n and 3n, but chromosome numbers in TDCB1 ranged considerably, from 2n to 5n, and there was a peak in 4n.

The survival of the developing eggs in several stages is presented in Table 2. Due to a heavy mortality in TDCB2 and TD1, larvae were too few to be sampled for collecting data. The survival of treated groups varied greatly. At 6 days after fertilization, the mean survival rate was 24.01% of the total number of D-stage larvae cultured. At Day 22, only 2.05% of larvae survived. At Day 51, 2125 spat of 0.5cm in size were harvested. In TDCB1, 355 spat were harvested (0.0295% of D-larvae cultured), 737 spat in TDCB3 (0.0164% of D-larvae cultured), 1033 spat in TDCB4 (0.0531% of D-larvae cultured), the mean harvest rate was 0.033%.

After 1-year culture in the sea, shell length had reached 4 to 6 cm, 230 pearl oysters were sampled for size and weight, and ploidy determination. One hundred and fifteen pearl oysters had good chromosome metaphases and their ploidy was determined, the ploidy of others could not be determined due to too few metaphases. Among these 115 samples, two (1.74%) were tetraploids with 56 chromosomes, 33 (28.70%) were diploids, 47 (40.87%) were triploids, and 33 (28.70%) were aneuploids with 29, 30, 40, 41, and 43 chromosomes (Table 3). Representative

metaphases of ploypoids and aneuploids are presented in Figure 2.

Analysis of *t*-test showed that triploids were significantly bigger than diploids ($P < 0.05$), supporting our previous findings (Jiang et al. 1991). Aneuploids were significantly smaller than triploids in mean shell length and body weight ($P < 0.05$), but were not significantly different from diploids ($P > 0.1$) (Table 4) One tetraploid had the size of 5.38 cm in SL and 22.2g in BW, one was 5.35 cm in SL and 21g in BW. The body weight distribution of 115 samples is presented in Figure 3.

DISCUSSION AND CONCLUSIONS

Triploid shellfish are commonly assumed to be sterile due to their retarded gonadal development. Retarded gonadal development and abnormal gametogenesis have been confirmed in *Pinctada martensii* (Komaru and Wada 1990; Jiang et al. 1990) and several other species. It is interesting that some female and male triploids in mollusks can produce numeral gametes and fertilize with normal diploids, even produce offspring (Allen 1987; Allen and Downing 1990; Guo 1991; Komaru and Wada 1994; He et al.1996). In this study, 2-year-old triploid females had between 2.07 and 61.92 million eggs. Reasonable fecundity in triploid females makes it possible to produce tetraploids through this technique, but this maybe puts breeders in the unusual position of needing non-reproductive triploids for commercial culture. However, the previous research has demonstrated that the daily growth rate of triploids is obviously greater than that of diploids during the reproductive period, and there is no significant difference in most months of the non-reproductive period (Jiang et al. 1991). This result implies that a small proportion of matured triploids has no obvious effect on the advantage of faster growth. On the other hand, retarded gonadal development is not the only reason why triploids grow faster than diploids.

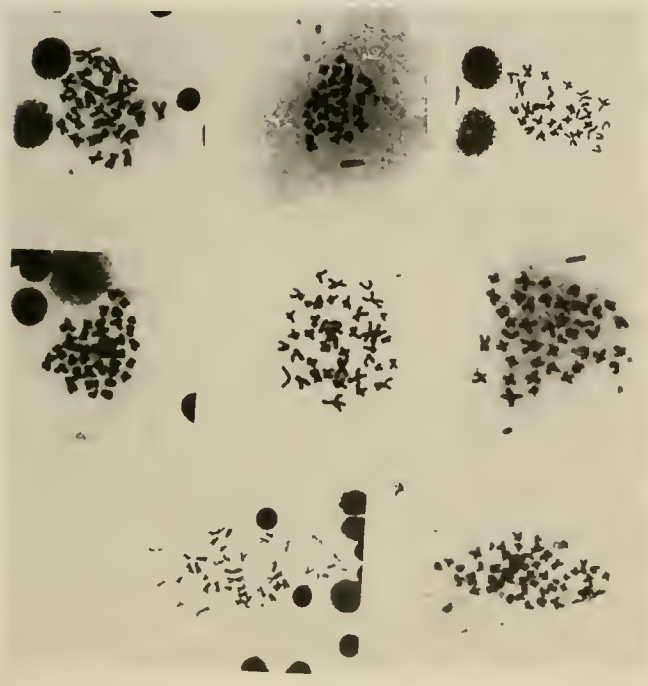

Figure 2. Representative metaphases of adult *Pinctada martensii* (D.). A: 2n = 28, B: 2n + 1 = 29, C: 2 n + 2 = 30, D: 3n − 2 = 40, E: 3n − 1 = 41, F: 3n = 42, G: 3n + 1 = 43, H: 4n = 56.

The TD cross primarily produced aneuploid embryos with chromosome number between 28 and 42, with an average ploidy of 2.5n (35 chromosomes), which agrees with previous observations (He et al. 1996). However, no larvae survived through metamorphosis in our experiments. An exception is that juvenile Japanese pearl oysters, *Pinctada fucata martensii* (a subspecies, Jiang et al. 1993), survived in TD with ploidy of 2n and 3n (Komaru and Wada 1994). This result differs from the ploidy composition (2n, 3n, and 4n) of Pacific oyster offspring in TD (Guo and Allen 1994b). In TDCB, tetraploid embryos were 16.69%, yet at adult age, only 1.74% of tetraploids survived. But, 67% tetraploid Pacific oysters were produced by this method (Guo and Allen 1994a). The percentage of adult aneuploid was 28.70%, smaller than that of early embryo stage. The ratio of diploid and triploid in adult age increased to 69.57% from 16.37% in early embryo stage. Spat harvested were about 0.033% of D-stage larvae cultured. These data suggested that most of tetraploids and aneuploids died during rearing or culturing. Guo and Allen (1994a) reported that spat of Pacific oysters were harvested from only one of three replicates, which were about 0.0738% of the developing eggs. These showed there was a heavy mortality of larvae produced by crossing triploid females and diploid males. It is concluded that lower fecundity of triploids and lower survivorship of larvae may restrict the potential of this technique for producing viable tetraploids.

Guo (1991) suggested that the inviability of induced tetraploid oysters might be due to a cell-number deficiency caused by the cleavage of eggs of normal volume with a large, tetraploid nucleus. In oysters and most other mollusks, development is mosaic. Unlike shellfish, tetraploid fish and amphibians have been obtained; their

TABLE 4.

Comparison of body size and weight between aneuploids and euploids in *Pinctada martensii* (D.).

Ploidy	Chromosome numbers	Individuals observed	Body weight (SE)/g	Shell length (SE)/cm
Diploid	28	33	23.38 (4.75)	5.07 (0.40)
Triploid	42	47	28.01 (7.80)	5.37 (0.65)
Aneuploid		33	20.62 (7.83)	4.91 (0.78)
Tetraploid	56	2	21.60 (0.85)	5.37 (0.02)

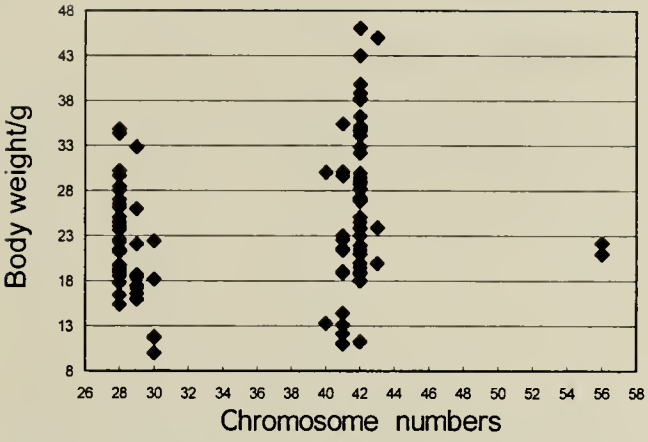

Figure 3. The body weight distribution of *Pinctada martensii* (D.) with different chromosome numbers.

development is not affected by the cell number deficiency probably because the development is regulative. The problem of cell number deficiency in tetraploid embryos might be eliminated by an increase in the egg volume. Eggs from triploids are larger than eggs of diploids, probably led to a significant reduction in cell number deficiency and therefor the survival of tetraploids. Production of viable tetraploid Pacific oysters (Guo and Allen 1994a) and pearl oysters in this study supported the cell number deficiency hypothesis. But, why are tetraploids of *Mytilus galloprovincialis* and *Tapes philippinarum* produced from eggs of diploids viable, whereas tetraploid Pacific oysters and pearl oysters produced from diploid eggs are not? Eggs of *Mytilus galloprovincialis* have a diameter of about 66–70 μm and eggs of *Tapes philippinarum* are 55–60μm, larger than the diameter of eggs from Pacific oysters (47.8 μm) and pearl oysters (50 μm). The remarkable increase in egg volume may account for it. It may reflect species-species difference in tolerance to tetraploidy. Although only two tetraploids were produced in this study, this finding indicated that tetraploidy can be tolerated in *Pinctada martensii* (D.), and demonstrated that this method of producing tetraploids is viable.

It is seen that inhibition of the first body release increased the ratio of polyploid embryos, which maybe result from a variety of segregation patterns in meiosis (Guo et al. 1992b). Que et al. (1997) reported that the pattern of chromosome segregation in meiosis was changed when CB was applied to inhibit the polar body in eggs from triploids. Four types of segregation such as tripolar segregation, united bipolar segregation, separated segregation and incomplete united bipolar segregation were observed. Similar patterns of chromosome segregation were found in pearl oysters (unpublished data). Guo and Allen (1994a) and Que et al (1997) suggested the production of tetraploids was as a result of united bipolar segregation. According to this type of segregation, the united chromosome will undergo equational division, 42 chromosomes are rejected as the first polar body, and 42 chromosomes remain in the eggs, combining with haploid sperm (14 chromosomes) producing tetraploid. In the TD cross, the majority of fertilized eggs went through two meiotic divisions and released two polar bodies, the extra set of chromosomes segregated randomly.

In addition to ploypoid pearl oysters, this process also produced many aneuploids. This study provided another evidence that certain aneuploids are viable in shellfish. The viability of aneuploid has been reported in Pacific oysters (Guo and Allen 1994a; Wang et al. 1999) and Pacific abalone (*Haliotis discus hanni*) (Fujino et al. 1990). The data showed that aneuploid pearl oysters, as a group, are not significantly different from diploids in shell length and weight. In contrast, aneuploid Pacific abalone shows no growth retardation, actually they are bigger than normal diploids (Fujino et al. 1990); aneuploid Pacific oysters (3n ± n) are larger than diploids (Wang et al. 1999), but probably because of their triploidy, not aneuploidy.

It is interesting to note one pearl oyster with 43 (3n + 1) chromosomes is the largest in body size and the second largest in body weight in this study. Guo and Allen (1994a) reported that one of the aneuploid oysters with 38 (4n - 2) chromosomes is the largest by whole body weight. These findings suggested that some aneuploids have the growth advantage and the potential application to aquaculture through breeding and selection. Certain aneuploids may also be useful in genetic manipulation. For example, trisomics and monosomics are of use of the gene transfer or gene identification. The use of aneuploid has successfully lead to the transfer of leaf rust resistance from a wild grass (*Aegilops umbellulata*) to wheat (Sears 1956).

Further research will focus on the growth and use of aneuploid pearl oysters, and on how to raise the survival rate of tetraploids.

EVALUATION OF FIVE MICROALGAL SPECIES FOR THE GROWTH OF EARLY SPAT OF THE JAPANESE PEARL OYSTER *PINCTADA FUCATA MARTENSII*

KATSUYUKI NUMAGUCHI
National Research Institute of Fisheries Science
6-31 Nagai, Yokosuka
Kanagawa 238-0316, Japan

ABSTRACT To estimate the food value of five microalgal species, early spat of the Japanese pearl oyster, *Pinctada fucata martensii*, were fed five algal species separately; *Pavlova lutheri*, *Chaetoceros calcitrans*, *Tetraselmis tetrathele*, *Nitzschia closterium*, and *Nannochloropsis oculata*. The food value of each microalgal species was estimated from the growth rate of hinge length, dry whole spat, dry shell weight, and dry flesh weight of spat fed each microalgal diet over 19 days in the laboratory. *C. calcitrans* produced the best growth of the pearl oyster spat. *P. lutheri* and *T. tetrathele* supported moderate growth of the spat. However, growth rate of the spat fed *Nitzschia closterium* was very low and spat fed *Nannochloropsis oculata* showed negligible growth. These results indicate that *C. calcitrans* is an appropriate microalgal diet for rearing pearl oyster spat. *P. lutheri* and *T. tetrathele* are also suitable diets for rearing early spat of pearl oysters.

KEY WORDS: Pearl oyster spat, microalgal diet, growth

INTRODUCTION

Microalgal plankton is the principal food source for bivalves. There have been many studies on the nutritional value of cultured microalgae and their promotion of growth in marine bivalves larvae, spat, and juvenile (*Ostrea edulis*, Enright et al. 1986a, Walne 1963; *Crassostrea virginica*, Davis and Gullard 1958; *Saccostrea commercialis*, Nell and O'Connor 1991, O'Connor et al. 1992; *Pinctada fucata martensii*, Wada 1973, Okauchi 1990; *Crassadoma gigantea*, Whyte et al. 1990; *Ruditapes philippinarum*, Sakai and Toba 1994).

Pavlova lutheri (Droop) Green is the most popular microalgal species in Japanese bivalve culture and seed production studies (*Scapharca broughtonii*, Ohhashi and Kawamoto 1980; *Pinctada fucata martensii*, Hayashi and Seko 1986; *Ruditapes philippinarum*, Miyama and Toba 1990, Taba and Miyama 1993; *Meretrix lamarckii*, Shitomi and Kodama 1987a, Yanagida and Kodama 1988; *Pseudocardium sachalinense*, Shitomi and Kodama 1987b, Yanagida et al. 1988).

In a previous study, I reconfirmed that *Pavlova lutheri* is a suitable microalga for the growth of early spat of pearl oyster, *Pinctada fucata martensii* (Numaguchi 1999). However, there is little information that evaluates other microalgal species for the growth of pearl oyster spat. The aim of this study is to evaluate five microalgal species as diets for pearl oyster spat.

MATERIALS AND METHODS

Pearl Oyster Spat

Pearl oyster spat used were produced in the Pearl Oyster Seed Production Center of the Nagasaki Pearl Oyster Fisheries Cooperative Association. Spat were obtained approximately 3 months after fertilization in the hatchery. Average hinge length of the spat was about 3.5 mm. These spat were reared for 2 weeks in a 30-L aquarium with water temperature 26–27 °C, salinity 30–32 ppt and fed an algal diet of *Pavlova lutheri*.

Microalgae

The algal species used are shown in Table 1. Algal cultures were produced axenically in 5-L glass flasks using modified Erd–Schreiber medium: 100 mg $NaNO_3$, 20 mg $Na_2HPO_4 \cdot 12H_2O$, 50 mg $NaSiO_3$, 100 mg Nitrilotriacetic (NTA), 100 mg Tris (hydroxymethyl) aminomethane, 0.4 μg Vitamin B_{12}, 100 μg Thiamin, 1 μg Biotin, 5 mg Clewat 32 (Teikoku Kagaku Ltd, Japan; 1 g Clewat 32 contains 3.8 mg Fe, 7.7 mg Mn, 1.6 mg Zn, 0.07 mg Cu, 6.3 mg Mo, 24.7 mg B, 0.23 mg Co, and some EDTA) in 1-L of 4/5 diluted seawater. The medium was adjusted to pH 7.8 and sterilized by autoclaving (121 °C, 15 min). All species were batch cultured at 20 °C with 24-h illumination at an intensity of 5,000 lux.

Because cell size and volume differed for each of these microalgae, cell size and weight were measured for each species. Their sizes were measured using a Coulter Counter (Model ZB) and a Coulter Channelyzer-(Model C-100; Coulter Electronics Inc, USA). The range and mode of cell diameter for each algal species was estimated from the histogram of algal cell volume from Coulter Channelyzer, and the dry weight of each algal species was determined as follows. Initially, the algal cell concentration was determined using a Coulter Counter. A known volume (20–50 mL) was then filtered though a GF/C glass fiber filter (Whatman Ltd, England), which was preheated for 2 h at 500 °C to remove organic substances, to collect the algal cells. The filter was washed with 0.9% ammonium formate solution to remove salt and dried at 110 °C for 24 h. The dry cell weight was then calculated using the algal cell concentration and total weight of filtered cells. The dry weight of suspended solids in the seawater used for the experiment was also determined this way.

Experimental Design

Twenty spat were allocated to each 2-L beaker aquarium with seawater filtered with 1 μm cartridge filters. During the experi-

TABLE 1.

List of microalgal diets used for the experiment and their cellular characteristics.

Phytoplankton	Volume[1] (μm^3)	Cell Diameter[2] Range (μm)	Mode of Cell[2] Diameter (μm)	Dry Weight[3] of Cell (pg/Cell)
Haptophyceae				
Pavlova lutheri (Droop) Green	57	4.5–5.6	4.8	32.5 ± 2.6
Bacillariophyceae				
Chaetoceros calcitrans (Paulsen) Takano	56	4.5–5.6	4.8	70.3 ± 4.1
Nitzschia clasterium (HER.) W.Smith	64	4.8–7.3	5.0	30.9 ± 1.6
Prasinophyceae				
Tetraselmis tetrathele (West) Butcher	335	8.0–10.7	8.6	251 ± 10
Eustigmatophyceae				
Nannochloropsis oculata (Droop) Hibberd	9	2.3–3.5	2.6	4.9 ± 0.1

[1] Cell volume was measured by Coulter Counter and Coulter Channelyzer.
[2] Cell diameter range and mode were calculated by the equation of a spherical body from the cell volume histogram measured by the Coulter counter and Coulter Channelyzer.
[3] Values are means ± SD (n = 5).

ment, the dry weight of suspended solids in the filtered seawater was 1.54 ± 0.56 mg/L (n = 4), water temperature was 26–27 °C and salinity was 30–32 ppt.

Feeding trials, including an unfed control, were carried out over 19 days. Insufficient feeding will give false evaluations of food value of the microalgae for the growth of pearl oyster spat, so each feeding diet was supplied in excess in this experiment. Numaguchi (1999) showed that the optimal feeding concentration of *Pavlova luteri* was 2×10^4 cells/mL for maximum growth of pearl oyster spat at 2.6–3.0 mm hinge length. In this experiment, three times the concentration of *P. lutheri* (6×10^4 cells/mL) was fed to pearl oyster spat of 3.5 mm hinge length. Other algal concentrations were calculated from same packed cell volume as one of *P. lutheri*, the packed cell volume calculated to product of cell concentrations and cell volume. The feeding concentration of each algal species was set as follows; *P. lutheri* 6×10^4 cells/mL, *Chaetoceros calcitrans* 6.1×10^4 cells/mL, *Tetraselmis tetrathele* 1×10^4 cells/mL, *Nitzschia closterium* 5.4×10^4 cells/mL, and *Nannochloropsis oculata* 37.5×10^4 cells/mL.

Each algal diet was added to the relevant beaker each morning at the above concentrations. Seawater in each beaker was changed every day just before feeding to remove the remaining algae that might have negatively affected feeding. Over the rearing period, spat were observed to determine whether they were alive or dead. Spat attached to the aquarium wall were regarded as alive, and unattached spat, those with no viscera, or only a shell were regarded as dead. Dead spat were counted and removed from the aquarium.

Spat Growth Measurement

Hinge length of each spat was measured at the beginning and end of the feeding experiment using a stereoscopic microscope with a micrometer. Growth rate of spat hinge length per day was calculated as follows:

Growth rate of hinge length (μm/day) = (final average hinge length – initial average hinge length) / rearing duration

To measure the dry weight of whole spat, the spat shell, and spat flesh, ten spat were collected randomly from each aquarium at the beginning and end of the feeding experiment. Each spat was washed in 0.9% ammonium formate solution to remove salts and was wiped with paper towel. Dry whole spat weight was measured after spat were dried at 110 °C for 24 h on a platinum board. Dry shell weight was measured after drying the spat on a platinum

TABLE 2.

Growth of hinge length and mortality of pearl oyster spat.

Diet	Hinge Length (μm) Initial (0 Day)[1]	Hinge Length (μm) Final (19 Day)[1]	Growth Rate (μm/Day)	Mortality (%)
Chaetoceros calcitrans	3,405 ± 296[a] (n = 20)	8,745 ± 1,285[d] (n = 20)	281	0
Pavlova lutheri	3,443 ± 337[a] (n = 20)	6,217 ± 881[c] (n = 18)	146	10
Tetraselmis tetrathele	3,510 ± 518[a] (n = 20)	6,183 ± 921[c] (n = 18)	141	10
Nitzschia closterium	3,338 ± 373[a] (n = 20)	4,587 ± 962[b] (n = 19)	66	5
Nannochloropsis oculata	3,653 ± 330[a] (n = 20)	3,683 ± 351[a] (n = 18)	2	10
Unfed control	3,525 ± 360[a] (n = 20)	3,563 ± 346[a] (n = 15)	2	25

[1] Values are means ± SD, values within a column with different superscripts were significantly different (Duncan multiple range test, $P < 0.05$).

TABLE 3.

Dry weight gain of whole spat, shell, and flesh of pearl oyster spat.

Diet	Whole Spat[1] (μg)	Shell[1] (μg)	Flesh[1] (μg)
Initial (0 day)	1,470 ± 533	1,255 ± 452	215 ± 83
Final (19 days)			
Chaetoceros calcitrans	16,709 ± 6,250[c]	14,015 ± 4,990[c]	2,694 ± 1,302[c]
Pavlova lutheri	9,785 ± 4,180[b]	8,280 ± 3,484[b]	1,505 ± 718[c]
Tetraselmis tetrathele	7,979 ± 3,994[b]	6,852 ± 3,185[b]	1,127 ± 819[bc]
Nitzschia closterium	3,907 ± 1,447[a]	3,297 ± 1,202[a]	610 ± 275[b]
Nannochloropsis oculata	2,308 ± 674[a]	2,188 ± 548[a]	120 ± 140[a]
Unfed control	1,679 ± 410[a]	1,556 ± 389[a]	123 ± 53[a]

[1] Values are means ± SD (n = 10), values within a column with different superscripts were significantly different (Duncan multiple range test, $P < 0.05$).

board at 500 °C for 6 h in a muffle furnace to burn away the flesh. Dry whole and shell weight of each spat was weighed to the nearest 1 μg using a Micro Balance (Mettler Type M-3; Mettler Toledo, Switzerland). Dry flesh weight was calculated by subtracting dry shell weight from dry whole weight. Growth rates for the whole spat, shell, and flesh, in dry weight per day, was calculated as follows:

Growth rate of weight (μg/day) = (final average dry weight – initial average dry weight) / rearing duration

RESULTS

Table 2 shows hinge length of the spat at the beginning and end of the experiment and growth rate and mortality of the spat during the experiment. *Chaetoceros calcitrans* produced the best growth of the pearl oyster spat in this feeding experiment. Although growth rates of the spat fed *Pavlova lutheri* and *Tetraselmis tetrathele* were about half those fed *C. calcitrans*. *P. lutheri*, and *T. tetrathele*, both supported good growth rates of pearl oyster spat. Spat growth rate with *Nitzschia closterium* was poor. Moreover, there was almost no growth of pearl oyster spat fed *Nannochloropsis oculata*. There was no mortality of the spat fed *C. calcitrans* and 5–10% mortality of the spat fed *P. lutheri*, *T. tetrathele*, *Nitzschia closterium*, and *Nannochloropsis oculata*. In contrast, mortality of the unfed control was rather high (25%).

Weight gain of dry whole spat, dry shell, and dry flesh was greatest for the spat fed *Chaetoceros calcitrans*. Weight gain of the spat fed *Pavlova lutheri* and *Tetraselmis tetrathele* was moderate. Whereas, weight gain of the spat fed *Nitzschia closterium* was poor. However, spat fed *Nannochloropsis oculata* and the unfed control had very low weight gain (Table 3). Figure 1 shows the growth rate of dry spat weight, dry shell, and dry flesh of the spat fed various microalgal diets along with the unfed control. The spat fed *C. calcitrans* had the highest growth rate compared to the other microalgal species. In decreasing order, diets of *P. lutheri*, *T. tetrathele*, and *Nitzschia closterium* promoted the growth of pearl oyster spat. The spat fed *Nannochloropsis oculata* had a negative growth rate as did the unfed control.

DISCUSSION

Good growth rates of the bivalve are obtained with various algal cell because of their appropriate cell size for ingestion, their susceptibility to mechanical or enzymatic digestion by bivalves, their nutritive and biochemical composition, and their lack of toxic cell metabolite (Babinchak and Ukeles 1979).

In this experiment, *Chaetoceros calcitrans* was the superior microalgal species for maximum growth rate of pearl oyster spat. Although *Pavlova lutheri* and *Tetraselmis tetrathele* were inferior diets to *C. calcitrans*, these species supported a moderate growth rate of pearl oyster spat. These results indicate that *C. calcitrans* is an appropriate microalgal diet for rearing pearl oyster spat; whereas, *P. lutheri* and *T. tetrathele* are also suitable diets for this species. However, *Nitzschia closterium* was an unfavorable diet for the growth of pearl oyster spat. *Nannochloropsis oculata* did not promote the growth of pearl oyster spat, suggesting it is an inappropriate diet for rearing pearl oyster spat. Wada (1973) also showed that *Chlorella* sp. (now classified as *Nanochloropsis*) was a poor diet for pearl oyster larvae. Walne (1963) indicated that *Chlorella stigmatophora*, which has cell wall, is of little value as food for oyster, *Ostrea edulis*, larvae. Babinchak and Ukeles (1979) also described that the cell wall of *Chlorella autotropphica* was resistant to enzymatic breakdown by the digestive system of larvae of the oyster, *Crassostrea virginica*. *Nannochloropsis oculata* may be similarly resistant to mechanical or enzymatic digestion by pearl oyster spat.

The biochemical composition and nutritional components of microalgae differ between species (Parsons et al. 1961, Epifanio et al. 1981, Enright et al. 1986b, Whyte 1987). O'Connor et al. (1992) found that suitable dietary algal species were different for different growth stages of the same bivalve species. For the pearl oyster, Wada (1973) indicated that *P. lutheri* was a more suitable algal diet than *C. calcitrans* for larvae; however, for the spat in this experiment, *C. calcitrans* was a more suitable diet than *P. lutheri*. Furthermore, Okauchi (1990) found that *Isochrysis gracilis* was suitable algal diet for pearl oyster juveniles. These results suggest that the nutritional demands of the pearl oyster may change with its growth stage.

ACKNOWLEDGMENTS

The author expresses gratitude to Dr. T. Horii, National Research Institute of Fisheries Science, for statistical analysis of the data. This study was supported in part by grants-in-aid from the Ministry of Agriculture, Forestry, and Fisheries, Japan.

COMBINED EFFECTS OF TEMPERATURE AND ALGAL CONCENTRATION ON SURVIVAL, GROWTH AND FEEDING PHYSIOLOGY OF *PINCTADA MAXIMA* (JAMESON) SPAT

DAVID MILLS

Darwin, Northern Territory, Australia

ABSTRACT To determine a suitable culture environment to maximize growth and survival, *Pinctada maxima* spat were held at 36 combinations of temperature and algal concentration for 14 days within a flowthrough system. Survival was greatest between 23 °C and 32 °C, with 35 °C resulting in high mortalities. The optimum temperature range for *P. maxima* spat found in this study agrees well with the observed temperatures which limit the natural distribution of *P. maxima* in Australian waters. Survival of spat was highest at low algal concentrations. Growth was optimal between 26 °C and 29 °C and at 54 algal cells μL^{-1}; however, growth was still acceptable at algal concentrations as low as 12 cells μL^{-1}. The organic content increased with feeding rate and was positively correlated with specific growth rate. Spat filtration rate declined at high feeding rates, whereas grazing rate increased, with a commensurate decline in conversion efficiency. It is recommended that *P. maxima* spat be maintained within the temperature range of 26 °C to 29 °C and at algal cell densities between 12 and 54 cells μL^{-1} to maximize spat performance and minimize algal wastage.

KEY WORDS: *Pinctada maxima*

INTRODUCTION

Following high mortalities of adult silver-lip pearl oysters, *Pinctada maxima* (Pass et al. 1987), during the 1970s and early 1980s, there has been a focus on hatchery production for ongrowing and pearl production (Rose et al. 1990). Although there has been considerable work published on *P. maxima* spat production and husbandry, there has been no published investigation into the role of either temperature or food concentration on spat culture success.

Temperature is regarded as one of the most potent factors affecting growth and metabolism of marine poikilotherms (Griffiths and Griffiths 1987) and has been shown to effect many physiological processes of bivalves, such as filtration, feeding, respiration, reproduction, and growth (Bayne et al. 1976).

There is evidence that the Australian distribution of both *P. margaritifera* and *P. maxima* is limited to areas where seawater temperatures range from 18 °C to 32 °C (Hynd 1955, Pass et al. 1987). High mortalities of up to 80% of wild fished *P. maxima* in Western Australia (WA) in the late 1970s and early 1980s were attributed to reduced disease resistance during periods of low temperature (Pass et al. 1987). This effect may have been enhanced by the change in temperature (from 19 °C to 26 °C) between the collection grounds and the farms during transportation.

Rose et al. (1990) investigated the seawater temperatures of the main Western Australian fishing beds for *P. maxima* and recorded bottom temperatures of between 20 °C and 26.8 °C. Surface temperatures showed a larger range (19.8–32.3 °C).

There have been several feeding rates used for *P. maxima* spat, without any real evidence as to their suitability. Rose (1990) recommended twice-daily feedings of 55–65 cells μL^{-1}, whereas Rose and Baker (1994) fed spat a mixed algal diet at 40–285 cells μL^{-1} depending on spat size. The algal concentration dynamics in a batch-fed system will vary with tank size, stocking density, and feeding frequency.

The aim of this experiment was to quantify the effects of temperature and food availability on the growth, survival, and feeding of *P. maxima* and to determine suitable regimes for spat culture.

Materials and Methods

Experimental animals

P. maxima spat were obtained from the Darwin Hatchery Project on December 17, 1996. These spat averaged 11 ± 0.7 mg with an initial organic content of 10.9%. Mean initial shell height (dorsoventral measurement) was 4.3 mm and ranged from 3.3 to 5.2 mm.

System

The system used in this experiment was a modified and scaled-up version of that described in Mills (1997). There were three experimental blocks, each consisting of six 100-L temperature-controlled waterbaths and six elevated 100-L reservoirs. Each reservoir contained an algal suspension at one of the experimental concentrations and supplied one replicate in each waterbath through a submersible pump and 4-mm tubing manifold. The flow rate into each replicate was controlled with 2-L h^{-1} irrigation drippers. Thus, each waterbath in each block contained one replicate tray at each algal concentration, giving one replicate of each combination of temperature and food concentration per block and three replicates of each combination. Different-colored pegs were used to identify replicates of each algal concentration within a waterbath. Both the incoming air and algal suspension were preheated to the correct temperature before entering the replicates by first passing through approximately 4 m of the 4-mm supply lines coiled within the waterbath. Spat were held individually within histological cassettes, with 10 spat in each replicate tray.

Trays were supported by the rim in rectangular holes cut into a 32-mm-thick sheet of extruded polystyrene foam, which was floated within each waterbath and acted as both tray support and

Current address: Paspaley Pearling Co. P/L, P.O. Box 338, Darwin, NT 0801, Australia.

insulator. Irrigation drippers and trays were replaced at weekly intervals to prevent fouling.

Outflow from each replicate was collected from a 4-mm tube connected to the tray outlet. A 60-μm mesh feces retainer prevented contamination of the outflow sample with feces and/or pseudofeces.

Temperatures and algal concentrations

There were six temperatures used in the experiment: 20, 23, 26, 29, 32, and 35 °C. This temperature range was chosen as it encompasses the annual range experienced in Darwin Harbour (23–32 °C) and is similar to that recorded at Broome (Rose et al.1990). The ambient room temperature was maintained at 20 °C (the minimum temperature attainable in the isothermal room), and all of the waterbaths at higher temperatures were heated with 300-W glass immersion heaters. Temperatures of the replicates were checked twice daily and maintained within ±0.5 °C of the desired experimental temperature. Standard errors of experimental temperatures were generally ±0.15–0.2 °C.

The initial algal concentrations delivered from the reservoirs were 10, 20, 40, 80, and 160 cells μL^{-1}, with unfed controls exposed only to filtered seawater. All seawater was filtered to 1 μm and then passed through a carbon filter to remove possible contaminants from the intake seawater, which was drawn from a commercial shipping wharf.

The algal concentration range was chosen to encompass the optimums found for *P. fucata* (Numaguchi 1994a, Krishnan and Alagarswami 1993) and for *P. maxima* by Bellanger (1995), and also the commonly used feeding rates in commercial hatcheries (80–100 cells μL^{-1}). However, the effective algal concentration surrounding the oyster may be better represented by the concentration in the outflow (Hildreth & Crisp 1976). That the outflow algal concentration was the same as that within the replicate was confirmed by comparing the algal concentration in samples taken from several replicates at 4-h intervals, with the subsequent concentration in the outflow. Thus, the results presented are given relative to the effective (outflow) rather than initial algal concentration. The mean effective outflow concentrations were 0, 6, 12, 23, 54, and 110 cells μL^{-1}. Algal feeding reservoirs were cleaned and refilled daily with the appropriate algal suspension.

Spat were fed an algal diet of equal cell numbers of Tahitian *Isochrysis* sp. (T. Iso) and *Chaetoceros muelleri*. These species have been shown to support good growth and survival of pearl oyster spat (Taylor et al. 1997, Southgate et al. 1998). Mean algal cell dry weights were 19 and 20 pg, respectively, and were determined by the method of Epifanio (1979). Algae was cultured in 20-L carboys using f/2 medium with a 12:12 photoperiod and harvested at the late exponential stage.

Preliminary trial

A preliminary trial was conducted to determine whether there was any change in the delivered algal concentration due to cell damage, growth or sedimentation, or differences in delivery volumes due to differing friction head loss within the system. One block was run over 24 hours without animals in the system at an initial algal concentration of 100 cells μL^{-1}. Outflow volumes and initial and final algal concentrations were compared by two-way ANOVA using a significance level (α) of 0.2.

There were no significant differences in either the volumes delivered ($P = 0.56$) or the outflow concentration ($P = 0.69$). Initial and final algal concentrations were not significantly different ($P = 0.78$). Subsequent trials showed that the volume of suspension delivered by a dripper was independent of the number of drippers on the manifold line at least up to $n = 8$. This occurs as the pumps used were not positive displacement, but rather maintained a set delivery pressure and possessed a delivery capacity exceeding that of the combined number of drippers. Thus, the number or status of drippers on a manifold line had no effect on the delivery pressure (and hence output) of individual drippers.

Sampling

As it was not logistically possible to weigh and measure all of the 1080 spat and sample all of the 108 outflows during a single day, both the startup and sampling procedures were sequenced over 3 days. A full block could not be sampled on 1 day, as there was not enough floorspace for all of the outflow collection vessels; hence, a part of each block was sampled on each day. The sequence used was designed to sample one replicate of each treatment combination on each day.

At days 7 and 14, each spat was removed from the histological cassettes, washed in seawater of the appropriate temperature to remove adherent feces, and then weighed to the nearest 0.1 mg and measured to the nearest 0.1 mm (DVH). Outflow volume and collection duration were recorded, and outflow samples were preserved with Lugols iodine for later counting and calculation of filtration and grazing rates.

Growth was expressed as the daily tissue weight specific growth rate (SGR) and was calculated according to the following equation:

$$SGR = (\text{Ln final tissue weight}) - (\text{Ln initial tissue weight})/\text{time [days]}) \times 100$$

The organic content was calculated as:

$$\text{Organic content (\%)} = \text{loss on ignition/dry weight} \times 100$$

Filtration rate (FR) was calculated by the formula of Bayne et al. (1976) for flowthrough systems:

$$FR\ (\text{l h}^{-1}) = CI - CO/CO \times F$$

where CI = the initial algal concentration, CO = the final algal concentration, and F = flow rate (l h^{-1}).

This was converted to a weight-specific filtration rate by the following equation:

$$FR\ (\text{l h}^{-1}\text{g}^{-1}) = FR\ (\text{l h}^{-1})/\text{tissue weight (g)}$$

Algal grazing rate for each replicate was calculated as:

$$\text{Grazing rate (\%)} = C\ (\text{g})/\text{dry tissue wt (g)}$$

Conversion efficiency was calculated by the equation:

$$\text{Conversion efficiency (\%)} = \text{SGR/grazing rate} \times \text{organic content of algae} \times 100$$

(modified from De Silva and Anderson 1995)

Statistical analysis

All responses to temperature and algal concentration were analyzed using a two-way factorial ANOVA model. Although samples for growth, filtration, and grazing rates were taken at weekly intervals, because of the plasticity of the spat organic content the analysis was conducted only on the final values, as these responses were all calculated relative to spat tissue weight.

There was very low survival at 35 °C (1.1%), and this temperature was excluded from subsequent analysis because of the low number of surviving individuals and hence very high selection pressure on the population.

Any survival percentage data that were not normally distributed was arcsine transformed before being analyzed (Underwood 1981).

Homogeneity of variances were tested with Cochran's test with the critical value (*CV*) calculated as:

$$CV = \text{largest variance}/\ \Sigma\ \text{variance}$$

and was compared with a tabulated value with (replicates/treatment) − 1 and (treatment levels − 1) degrees of freedom.

Normality of response distributions were tested on residuals (yij-Yi) using the Shapiro-Wilk W test (Zar 1984). If variances were found to be unequal, or the data had a non-normal distribution, appropriate transformations were done. Comparison of means was only undertaken if the overall ANOVA model was significant, using the Fisher's protected least significant difference test. Relationships between measured responses and culture conditions were examined using regression analysis. A P value <0.05 was considered significant for all statistical analysis.

Results

Survival

Both temperature ($P < 0.0001$) and algal concentration ($P = 0.03$) affected spat survival, with temperature being a much stronger influence than algal concentration. There was no significant interaction ($P = 0.16$). Within the naturally occurring temperature range for Darwin Harbour (23–32 °C), there was no effect of temperature on mortality rates, and survival was greater than 90% (Fig. 1). At 35 °C mortality was almost complete (98.9%), and at 20 °C survival was significantly lower than at 23 °C, 26 °C, 29 °C, and 32 °C.

Spat at the lowest algal concentration of 6 cells μL^{-1} showed the highest survival, which was significantly higher than those at 23 and 110 cells μL^{-1} and unfed spat (Fig. 2). It is notable that the only survival at 35 °C was at the lower algal concentrations (6 and 23 cells μL^{-1}).

Growth

Tissue SGR responded significantly to both temperature and algal concentration ($P = 0.0008$ and $P < 0.0001$, respectively), but there was no significant interaction ($P = 0.73$). Growth increased with increasing temperature up to 29 °C and then declined from 29 °C–32 °C (Fig. 3). The decrease in growth at 32 °C indicates that this is approaching the upper temperature limit for the species, as confirmed by the very low survival at 35 °C. Growth at 29 °C was more than twice that at 20 °C, and growth at 32 °C was similar to that at 23 °C. Tissue weights of unfed spat declined, indicating that there was no significant nutritional value in the filtered seawater. In fed spat, growth increased progressively with increasing algal concentration up to 54 cells μL^{-1}, after which there was a slight but nonsignificant decline (Fig. 4). Growth at 54 cells μL^{-1} was approximately 50% greater than that at 6 cells μL^{-1}. This illustrates that *P. maxima* spat are capable of moderate growth even at very low algal concentrations.

Organic content

Increases in algal concentration were reflected in significant increases in spat organic content ($P = 0.0002$), from 9.4% in unfed spat to >13% at the highest concentrations (Fig. 5). The organic content of spat cultured at 6 and 12 cells μL^{-1} was not significantly different from the initial value of 10.9%. Temperature had no significant effect on spat organic content ($P = 0.8$), nor was there any significant interaction between temperature and algal concentration ($P = 0.8$). There was a positive correlation between the SGR of spat and their organic content ($r^2 = 0.51$, P

< 0.0001), with faster-growing spat having a higher organic content.

Feeding

The two different algal species comprising the diet were counted separately in outflow samples obtained during the first week. There was no preferential selection by the spat for either of the species at any concentration or temperature, and the ratio of T. Iso to *C. muelleri* in the outflow was not significantly different from 1. Henceforth, for the calculation of feeding rates it was assumed that there was no selection for either species by the spat.

The weight-specific filtration rate increased with moderate increases in algal concentration up to 23 cells μL^{-1}, before declining significantly at 54 and 110 cells μL^{-1} (Fig. 6). Filtration rate was highest at 20 °C (54 L $h^{-1}g^{-1}$) and declined significantly with increasing temperature to 17.3 L $h^{-1}g^{-1}$ at 32 °C (Fig. 7). This is an inverse response to that shown in most bivalve studies, in which

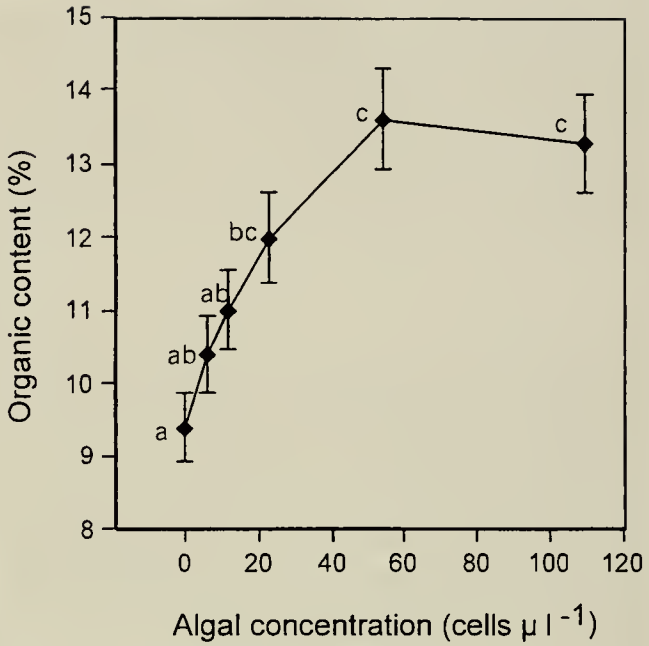

Figure 5. Organic content (% of dry weight) of *P. maxima* spat after 14 days at various algal concentrations. Figures show means ± standard error. Means with similar subscripts are not significantly different ($P > 0.05$).

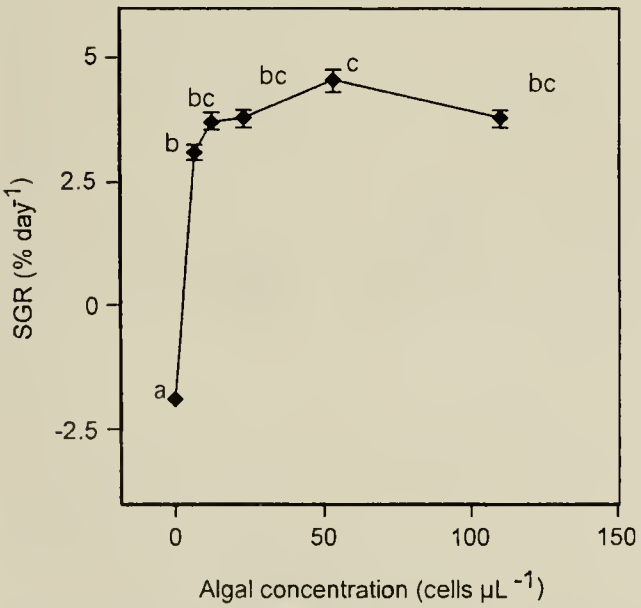

Figure 4. SGR of *P. maxima* spat after 14 days at various algal concentrations. Figures show means ± standard error. Means with similar subscripts are not significantly different ($P > 0.05$).

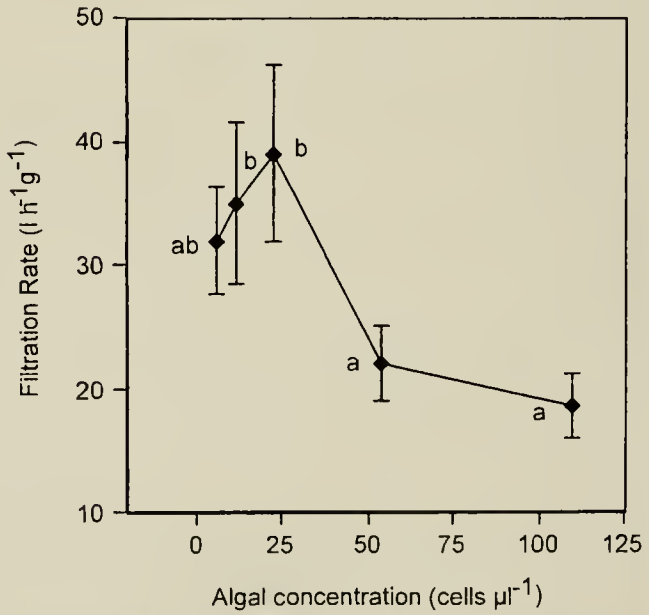

Figure 6. Filtration rates of *P. maxima* spat at various algal concentrations. Figures show means ± standard error. Means with similar subscripts are not significantly different ($P > 0.05$).

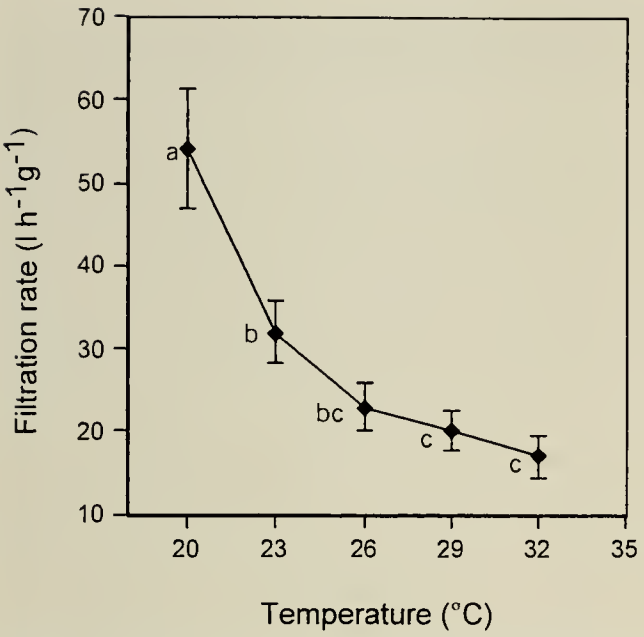

Figure 7. Filtration rate of *P. maxima* spat at different temperatures. Figures show means ± standard error. Means with similar subscripts are not significantly different ($P > 0.05$).

filtration rate generally increases with increasing temperature up to a maximum, with a subsequent decline.

The grazing rate (G) increased linearly with increasing algal concentration from approximately 15% at 6 cells μL^{-1} to 136% at 110 cells μL^{-1} following the equation:

$$G\% = 0.74 \times \text{algal concentration} + 18.2 \ (r^2 = 0.96) \text{ (Fig. 8)}$$

With the increase in grazing rate, there was a corresponding decline in the gross conversion efficiency from approximately 38% at 6 cells μL^{-1} to 5% at 110 cells μL^{-1} (Fig. 8). As the production of pseudofeces was not quantified, the gross conversion efficiency refers to growth from algae grazed, rather than ingested. The logarithmic decline in conversion efficiency (CE) can be described by the equation:

$$CE = [128.4 \times \text{algal concentration (cells } \mu L^{-1})]^{-0.745}$$

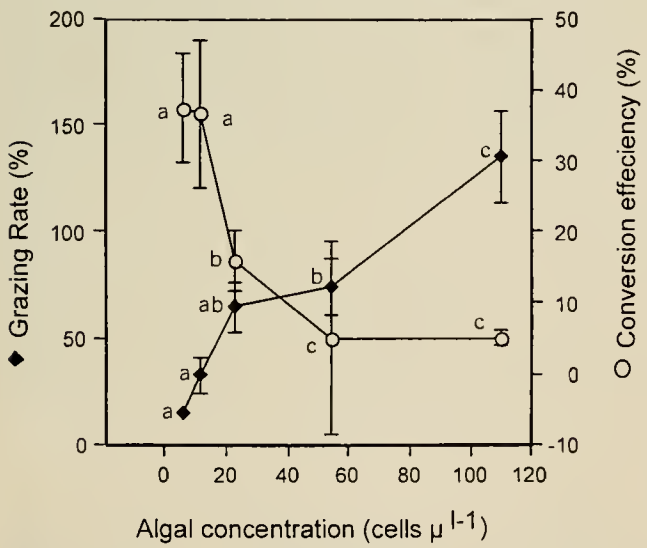

Figure 8. Grazing rate and conversion efficiency of *P. maxima* spat at different algal concentrations. Figures show means ± standard error. Means with similar subscripts are not significantly different ($P > 0.05$).

As the grazing rate increased greatly in response to increasing algal concentration without a commensurate increase in growth rate, it seems likely that the majority of the algae grazed were rejected as pseudofeces. Neither the grazing rate nor conversion efficiency was affected by temperature, nor was there any significant interaction of the two factors.

Discussion

Survival

The pattern of survival exhibited in this experiment is consistent with the observations of Pass et al. (1987), who concluded that the natural distribution of *P. maxima* was limited to areas with a seawater temperature range of 18–32 °C. Although it was not possible to examine the effects of temperatures below 20 °C, it is apparent from the significantly lower survival at 20 °C that the spat were approaching their lower tolerance limit. The very low survival at 35 °C indicates that this is above the upper tolerance limit, as foreshadowed by the reduced growth at 32 °C. The reduction in survival at 20 °C, and the very low survival at 35 °C, reflects the results of Doroudi et al. (1999) for *P. margaritifera* larvae, in which there was no development at either 20 °C or 35 °C. The optimum range for *P. margaritifera* larvae was found to be between 26 °C and 29 °C, which is slightly narrower than that found for *P. maxima* spat in the present study (23–29 °C). Numaguchi and Tanaka (1986) investigated the effects of temperatures from 7.5–35 °C on *P. fucata* and concluded that the lower and upper tolerance limits were 15 °C and 32 °C, respectively, with the optimum range being from 17.5 °C to 28 °C.

Temperatures on both the natural pearl oyster beds and pearl farms in WA would occasionally be high or low enough to be deleterious to *P. maxima* spat, as they generally range from 20 °C to 32 °C (Rose et al. 1990). In the Northern Territory (NT), summer inshore water temperatures are generally 31–32 °C from December to April (Padovan 1997) and may be approaching stressful temperatures. Wada (1953) observed that the temperature of the main deepwater commercial oyster grounds in the N.T. was the same throughout the water column and averaged 29 °C during the summer. The lower temperatures offshore may be more conducive to growth and reproduction than warmer inshore waters.

As surface seawater temperatures reach higher levels than bottom waters, pearl oysters hung from longlines (typically 1–3 m deep) may experience temperatures greater than 32 °C, especially in sites farther to the north such as the Kimberly region in northern WA, and the NT, and in calm sheltered bays. These temperatures may be at or near the tolerance limit of the species, and although there does not seem to be any direct mortality associated with them, there could be significant sublethal effects such as reduced growth, reproductive output, pearl quality, and resistance to stressors such as cleaning and handling. This may account for the lower-quality spawnings and gametes produced by oysters from farm longlines compared with those from the offshore fishing grounds (Rose et al. 1990), although this may be partly attributable to the frequent cleaning and handling of farm oysters.

High water temperatures may be more critical in NT hatcheries, as during the summer air temperatures commonly reach 34 °C, and this may be reflected in the temperature of the rearing tanks. Cur-

rently, the industry addresses this by shading of the seawater supply and rearing tanks; however, temperatures may still reach stressful levels. Stressed larvae and spat may be more susceptible to disease and suboptimal water quality. Algal cultures used to feed larvae and spat are grown at temperate water temperatures (20–24 °C), and problems may occur as a result of the abrupt increase in temperature experienced by the algae when it is transferred from the algal culture system to the spat culture tanks. Minaur (1969) noted that *P. lutheri* became moribund at temperatures above 30 °C and attributed this as a major problem in attempts to rear *P. maxima* larvae and spat.

Numaguchi (1994b) considered that an increase in the mortality rates of farm-held *P. fucata* was due to sustained elevated temperatures of greater than 28 °C. This may have been related to temperature stress combined with reduced food intake and higher metabolic costs, as the same author demonstrated that filtration rate declines dramatically at temperatures above 28 °C (Numaguchi 1994c), whereas catabolic losses increase at higher temperatures (Numaguchi 1995). There appears to be a similar process in *P. maxima*. Assuming that the organic content of the spat at day 7 was the same as that at the beginning of the experiment, then at 35 °C the mean filtration rate over all algal concentrations at 35 °C was 9.6 L $h^{-1}g^{-1}$ compared with >30 L $h^{-1}g^{-1}$ at temperatures from 20–32 °C. Unfed spat showed greater tissue weight loss with increasing temperature. This strongly suggests that if the experiment had been extended, there would have been large mortalities in unfed spat, particularly at the higher temperatures. The combination of these two factors indicate that at 35 °C there is reduced feeding and increased metabolic costs, leading to negative growth and increased mortality.

Algal concentration had a small but significant effect on spat mortality, with the survival rates at 6 cells μL^{-1} significantly greater than those of unfed spat and those at 23 and 110 cells μL^{-1}. The only surviving spat at 35 °C were unfed, and at the lower fed algal concentration. This is probably a result of the stimulatory response in filtration rate at higher algal concentrations (Fig. 6), resulting in an increase in metabolic rate and energetic costs, and consequently a more rapid loss of body tissue and death.

Growth

As previously found by Mills (1997), there was no significant relationship between the initial weight of spat and the subsequent SGR within the spat size range used ($r^2 = -0.11$, $P = 0.08$).

Increasing growth with increasing temperature up to an asymptotic point, followed by a rapid decline, is a common pattern for bivalves (Bayne et al. 1976). A similar pattern was shown by a temperate strain, *P. fucata* (Numaguchi and Tanaka 1986), exposed to temperatures ranging from 7.5 °C to 35 °C.

The relationship between preasymptote temperature and growth of *P. maxima* spat can be described by the second-order polynomial equation:

$$\text{Growth (SGR \% day}^{-1}) = -19.85 + 1.6 \text{ temperature} - 0.027 \text{ temperature}^2 \ (r^2 = 0.98)$$

From this equation, the calculated temperature of zero growth is 17.7 °C, which agrees well with the estimate of the lower temperature limiting the distribution of *P. maxima* by Pass et al. (1987) of 18 °C.

Growth relative to algal concentration showed a pattern similar to that obtained by Numaguchi (1994a) for *P. fucata* spat, in which growth increased rapidly up to a concentration of 20 cells μL^{-1}, with no advantage of further increases in concentration. In this study, growth increased rapidly up to 12 cells μL^{-1}, with further increases in concentration producing slightly higher growth. This lower threshold value for *P. maxima* may reflect the very high filtration rates attainable in this species. Yukihira et al. (1998b) calculated that the algal concentration for maximum scope for growth (SFG) of adult *P. maxima* was 20–30 cells μL^{-1}. Above this concentration the calculated SFG declined and was negative above 90 cells μL^{-1}. The decline was primarily due to a large reduction in the absorbed energy as a result of a decrease in absorption efficiency. Similarly, the SFG of *P. maxima* spat calculated by Bellanger (1995) predicted that growth would decline at T. Iso concentrations greater than 17 cells μL^{-1}. Although the results of the present study indicate that low algal concentrations may still promote good growth, there is no evidence that higher algal concentrations are detrimental. Bellanger (1995) could not separate pseudofeces from true feces, and consequently the absorption efficiency was underestimated. It is possible that spat may have different energetic characteristics than adults. Alternatively, there may be an acclimation to higher algal concentrations over time, which cannot be compensated for in short-term studies.

Preasymptotic growth at various algal concentrations can be described by the equation:

$$\text{Growth (SGR\% day}^{-1}) = 2.921 + 0.05 \text{ algal concentration (cells } \mu L^{-1}) - 3.795^{-4} \text{ algal concentration (cells } \mu L^{-1})^2 \ (r^2 = 0.93)$$

This equation predicts a maintenance ration (where SGR = 0) of 1.45 cells μL^{-1}. This value is substantially lower than that of Bellanger (1995), where the SFG was calculated to be 0 at 7.6 cells μL^{-1}. Given that growth was still quite high at 6 cells μL^{-1} in this experiment, the estimate obtained in this study would appear to be a more accurate estimate of the maintenance concentration. Yukihira et al. (1998a) calculated that the SFGs for *P. maxima* and *P. margaritifera* were very high even when exposed to very low algal concentrations (5 cells μL^{-1}). Hayashi and Seko (1986) monitored chlorophyll *a* levels and growth of *P. fucata* on pearl farms in Japan and concluded that maintenance requirements were met by algal concentrations that result in chlorophyll *a* levels of 3 $\mu g\ L^{-1}$, whereas levels of 4–5 $\mu g\ L^{-1}$ were required for good growth and reproductive development. This was equivalent to 6 and 10 cells μL^{-1} of *P. lutheri*, respectively. *P. fucata* appears to be adapted to more eutrophic conditions than *P. maxima*, as chlorophyll *a* levels in Darwin Harbour are generally from 0.5 to 3 $\mu g\ L^{-1}$ (Padovan 1997) and similarly low levels occur in the main fishing grounds off Broome (Rose et al. 1990). Mean chlorophyll *a* levels recorded at the Broome fishing grounds were from 0.3 to 0.9 $\mu g\ L^{-1}$ (Rose et al. 1990), equivalent to approximately 0.6–1.8 cells μL^{-1}. Thus, the calculated maintenance ration in this experiment agrees well with observed food levels in the field. The ability to thrive in conditions of very low food concentrations is due to the ability to process very large volumes of water (Yukihira et al. 1998a). As growth rates increased by 50% from 6 to 54 cells μL^{-1}, it may be that growth of oysters in the field is commonly food limited.

Organic content

Organic content is rarely determined in bivalve studies, and there are few references to pearl oyster spat. Given that spat organic content increased with both algal concentration and SGR, and that SGR increased commensurately with algal concentration, it is possible that the increase in organic content is related to the SGR rather than the algal concentration *per se*. This would agree

with the results of Taylor et al. (1997), who found that the organic content of *P. maxima* spat increased with higher SGR despite a reduced weight-specific ration fed to the fastest-growing spat.

Feeding

A limitation of the experimental method utilizing histological cassettes is that it is impossible to collect biodeposits; thus, the estimation of ingestion, absorption, and conversion efficiencies cannot be carried out. The filtration rates obtained in this experiment are very high compared with those of the previous experiment and other published filtration rates. This is probably due to the small size of the spat used, as the weight-specific filtration rate generally declines with increasing size according to the equation:

$$FR\ (\text{L h}^{-1}) = \text{aW}^{\text{b}}\ \text{(Bayne et al. 1976).}$$

Thompson and Bayne (1972) found that the weight exponent for mussels less than 1 g dry weight was higher than that of larger mussels. Thus, the very high filtration rates found in this study may reflect the very small spat used. Yukihira et al. (1998a) demonstrated that smaller *P. maxima* and *P. margaritifera* spat had a considerably higher filtration rate than larger animals. Using the equation developed by Yukihira et al. (1998a), $CR = 10.73\ W^{0.617}$, the predicted filtration rate for the mean final spat ash-free dry weight used in this trial (0.0023 g) would be 0.115 L h^{-1} compared with a measured value of 0.09 L h^{-1} .

Yukihira et al. (1998a) found that the filtration rates obtained for *P. maxima* and *P. margaritifera* were among the highest recorded for any bivalve species. A similar result was found for *P. margaritifera* by Pouvreau et al. (1999).

Reduction in filtration rate is a common response to increasing algal concentration (Bayne et al. 1976). The trends found in this study are similar to the findings of Bellanger (1995), in which algal concentrations above 17 cells μL^{-1} resulted in a decrease in the weight-specific filtration rate. In both cases, filtration rates initially increased with moderate increases in algal concentration and then declined at higher algal concentrations.

Reduction in filtration rate with increasing temperature is contrary to results from other studies on pearl oysters. Numaguchi (1994c) found that the filtration rate of 2-year-old *P. fucata* (5.7–6.1 cm shell height) increased with increasing temperature up to the tolerance limit before sharply declining. A similar pattern was shown for *P. fucata* spat (Numaguchi 1994a). The unusual results in this study are probably an artifact of the differences in size of the spat at the various temperatures, and a high rate exponent. Mean final dry tissue weight at 20 °C was 7 ± 1.5 mg and increased commensurately with temperature up to 21 ± 1.7 mg at 32 °C. Filtration rates of the largest spat (17 L $h^{-1}g^{-1}$ at 32 °C) approached those obtained by Mills (1997) of 7.3 L $h^{-1}g^{-1}$ and those of Bellanger (1995) (11.9 L $h^{-1}g^{-1}$). To eliminate any potential effects of different-sized spat, a short-term experiment would have to be conducted with similar-sized spat at all temperatures.

The lack of a temperature effect on grazing rate may also be an artifact of the variations in spat size at the different experimental temperatures, as the increase in filtration rate by smaller spat would have masked the increase in grazing rate with higher temperatures.

The increase in grazing rate with increasing algal concentration reflects the relatively low corresponding decrease in filtration rate. As growth did not increase proportionally, the extra algae grazed at higher algal concentrations was probably rejected as pseudofeces. This was consistent with observations that pseudofeces were produced at initial algal concentrations above 20 cells μL^{-1}. A similar observation was made by Bellanger (1995) at algal concentrations greater than 22 cells μL^{-1}. This increased rejection as algal concentration increases is reflected in the decrease in conversion efficiency from approximately 37% at 6 and 12 cells μL^{-1} to approximately 5% at 54 and 110 cells μL^{-1}.

Both the grazing and growth rates in this study are substantially higher than those recorded by Mills (1997), suggesting that growth is heavily dependent on food intake. This is consistent with the higher growth at higher algal concentrations.

In the present study the growth rate at 6 cells μL^{-1} was still quite high, although Bellanger (1995) predicted it to be negative. It is likely that the metabolic costs in that study were overestimated, leading to erroneous conclusions as to the predicted growth at various algal concentrations.

On the basis of the results of this study, *P. maxima* spat should be maintained at temperatures between 26 °C and 29 °C, and algal concentrations between 12 and 54 cells μL^{-1}. Within these culture parameters, spat growth and survival will be optimal, and the efficient utilization of algal cultures will be maximized.

ACKNOWLEDGMENTS

This research was funded by the Co-operative Research Centre for Aquaculture and supported by the Darwin Aquaculture Centre of the Department of Primary Industry and Fisheries, Northern Territory. The author is grateful to the staff of the Pearl Oyster Propagators and the Darwin Hatchery Project, who supplied the spat and microalgae.

ABSTRACT This study was carried out to investigate whether the cell surface charge of *Salmonella typhimurium* could influence the kinetics of uptake, distribution, and elimination in the blue mussel, *Mytilus edulis*. The bacteria (1 μm) were labeled with $^{99}Tc^{m}$ in the presence of stannous fluoride. Two different concentrations of stannous fluoride were used to produce differences in the cell surface charges of the bacteria. A set of mussels in the investigation were also given ^{113}Sn-labeled microspheres (15 μm) together with bacteria to compare the impact between particle size and cell surface properties on the distribution kinetics. The distribution of radiolabeled particles in the mussel was followed and analyzed with a computer-aided gamma camera that can detect two isotopes simultaneously. Finally, the mussels were dissected and the radioactivity in the fractions was measured with a well-shielded NaI(Tl) detector. The reduced cell surface charge of *S. typhimurium* enhanced the preingestive selection on the gills or labial palps as well as the postingestive selection in the digestive glands in such a way that it became similar to the microspheres, despite the size differences. The uptake of the bacteria labeled in the presence of less stannous fluoride was significantly lower. However, the subsequent absorption of these bacteria in the digestive gland was greater, because the recovery of radioactivity outside the digestive tract was higher than for the more manipulated bacteria and the microspheres. Likewise, the elimination of the more manipulated bacteria was similar to that of the microspheres and significantly higher than that of the less affected bacteria. It is concluded that the cell surface properties of bacteria, possibly the charge, influence the uptake, distribution, and elimination in *M. edulis* and that this factor could have the same influence as size on the uptake capacity.

KEY WORDS: *Mytilus edulis*, bivalves, molluscs, *Salmonella typhimurium*, gamma camera, $^{99}Tc^{m}$-labeled bacteria, surface, uptake, preingestive selection, postingestive selection

INTRODUCTION

Because of their efficient filter-feeding mechanism, bivalves are capable of accumulating large numbers of microorganisms from the surrounding water.

Problems related to microbes in terms of pathogenic bacteria and viruses in bivalves can be a major deterrent when developing a sustainable plan for utilization of coastal resources. The planktonic bacterium *Vibrio parahaemolyticus*, as well as bacteria associated with fecal pollution, such as *Salmonella*, *Shigella*, and *Clostridium spp.*, have caused numerous outbreaks of gastroenteritis in connection with consumption of seafood (Matches and Abeyta 1983, Rodrick and Schneider 1991, Wilson and Moore 1996). In addition, viruses, such as the small, naked viruses (e.g. Calici and Norwalk viruses), hepatitis A, and enterovirus, are considered as health hazards in utilizing bivalves for food (Sindermann 1990, Enriques et al. 1992, Cliver 1997). To improve risk assessment and develop satisfactory control methods in respect to public health, the basic knowledge about the regulating mechanisms for uptake, distribution, and elimination of microbes in bivalves has to be improved.

A study on filtration capacity of particles in *Mytilus edulis* (Møhlenberg and Riisgård 1978) showed a marked decline in the uptake of particles smaller than 7 μm, which fell to 20% at 1 μm. Also, it has been shown by Allison et al. (1998) that particles (3–40 μm) enriched in metals were rejected in *M. edulis*, and microalgal metabolites have been proved to influence mussel feeding behavior (Ward & Targett 1989). This indicates that the lamellibranch bivalves have some ability of preingestive selection, presumably on the gills or the labial palps, which is not only related to size but also to other particle characteristics. In addition, the possibility of postingestive selection in the digestive tract has been suggested (Shumway et al. 1985, Smith & MacDonald 1997). Digestion in invertebrates includes extracellular and intracellular digestion processes. The extracellular digestion is a fast process that dominates during intestinal digestion. It results in low absorption efficiency and poorly digested "intestinal" feces. The intracellular digestion is a slow process in the diverticular folds of the stomach. The epithelial cells of the folds phagocytose and digest small particles with high efficiency resulting in good absorption and well-digested "glandular feces" (Morton 1973, Decho & Luoma 1991). The hemocytes of the bivalves are also functioning in nutrient digestion and transport as well as in internal defense (Cheng 1984). They contain numerous lysosomes capable of releasing hydrolytic enzymes and reactive oxygen radicals (Winston et al. 1991). Birkbeck and McHenery (1982) showed that bacteria such as *Micrococcus roseus* and *Staphylococcus aureus*, resistant to the lysozyme of *M. edulis*, were rejected intact, whereas *Escherichia coli*, *M. luteus* and *Bacillus cereus*, which were sensitive to lysozyme, were killed after ingestion. Rögener & Uhlenbruck (1984) found that invertebrates recognized and bound so-called

heterophilic antigens or ubiquitous chemical structures such as lipopolysaccharides and zymosan, which are often present on the surface of microorganisms. This indicates that recognition of cell surface characteristics of the prey might be a regulating mechanism for selection in the digestive gland.

We hypothesize that not only size but also cell surface properties of particles might influence the uptake and the subsequent distribution and elimination of microorganisms in *M. edulis*. To test this, a gamma camera technique was used for *in vivo* recording of blue mussels with respect to uptake and elimination of radiolabeled *Salmonella typhimurium* (ca. 1 μm) and microspheres (15 μm). After the gamma camera experiment, the radioactivity in dissected fractions of the mussel tissue was measured with well-shielded NaI(Tl) detector to follow the distribution into different organs. The labeling procedure for *S. typhimurium* has been described in the previous study by Hernroth et al. (2000). Bacteria with different cell surface charges were obtained by using different concentrations of stannous fluoride.

MATERIALS AND METHODS

Bacterial Strain and Growth Conditions

S. typhimurium 395 MR10, a nonvirulent, chemotype-Rd mutant (Edebo et al. 1980) was grown for 16 h in glucose broth (Lindberg et al. 1970) (pH 7.0–7.2) at 37 °C on a rotary shaker (200 rpm). The bacterial suspension was washed three times by centrifugation (2000 rpm, 10 min, 4 °C) in 3 mL 0.9% NaCl to remove the culture medium. The pellet was resuspended in 2 mL 0.9% NaCl (2.5×10^9 mL^{-1}).

Radiolabeling and Chemical Modification of Bacteria

Stannous fluoride (SnF_2) was used to reduce $^{99}Tc^m$ to facilitate the labeling of the isotope (Perin et al. 1997). It also binds to protein structures intracellularly as well as at the cell surface (Rhodes 1991). It has been shown in a previous study by Hernroth et al. (2000) that stannous fluoride can chemically modify the cell surface charge of *S. typhimurium*. The bacteria showed differences in electrophoretic mobility when 80 μg SnF_2 and 800 μg SnF_2, respectively, were used in the labeling procedure. The mobility for bacteria treated with 80 μg SnF_2 (5.4×10^{-9} m$^2 \times$ V^{-1}s^{-1}) was not significantly different from untreated *S. typhimurium* (4.7×10^{-9} m$^2 \times$ V^{-1}s^{-1}), whereas the mobility for bacteria treated with 800 SnF_2 was significantly reduced (2.3×10^{-9} m$^2 \times$ V^{-1}s^{-1}). The same treatment to label bacteria with different cell surface properties was used for this study.

One milliliter of bacteria suspension (2.5×10^9 mL^{-1}) was mixed with 2 mL of 37 °C 0.9% NaCl containing 80 or 800 μg SnF_2 and then incubated with approximately 50 MBq $^{99}Tc^m$-pertechnetate for 20 min at 37 °C on a rotary shaker (200 rpm). After incubation, the bacteria were centrifuged and washed three times. Ascorbic acid (0.25 mg mL^{-1}) was added to the washing solution to prevent reoxidation of the reduced $^{99}Tc^m$. The bacteria were resuspended in 1 mL 0.9% NaCl.

To control the cell size and shape of *S. typhimurium* and observe possible formation of aggregates, the batches of labeled bacteria were inspected in a microscope (12.5 × 100× magnification) before feeding took place. As references, unlabeled *S. typhimurium* bacteria were used.

Viability of ^{99m}Tc-Labeled Bacteria

The viability of the bacteria was checked using a fluorescence assay (LIVE/DEAD *Bac*Light™ Bacterial Viability Kit, Molecular Probes, The Netherlands). Triplicates of $^{99}Tc^m$:80 and $^{99}Tc^m$:800 were compared with unlabeled bacteria from the same culture, using epifluorescence microscopy (Zeiss Axioscop, Exciterfilter BP450-490, Dichroic reflector 510, and Barrier filter LP5159, Zeiss, Germany). The suspension of bacteria was diluted to $10^6 \times$ mL^{-1} in sterile filtered (Schleicher & Schuell, Keene, NH, FP 030/3) seawater (32 PSU) and incubated with the fluorescence probe for 15 min at 12 °C. The intact plasma membranes of live bacteria give green fluorescence, whereas compromised membranes of dead ones give red fluorescence (Haugland 1996). The viable bacteria were calculated as part of 100 cells.

Mussel Experiment

The experiment was carried out during April and May 1998. Blue mussels, *M. edulis*, were collected at 1 m depth in the Åby Fjord, on the west coast of Sweden (tidal amplitude 20 cm). The salinity, when sampling, was 28 PSU, and the temperature was 6 °C. Mean shell length of the 32 mussels was 7.6 ± 0.8 cm, shell width was 3.4 ± 0.7 cm, and flesh wet weight was 11.6 ± 3.5 g. The mussels were cleaned from epiphytes and stored in running seawater (32 PSU and 8 °C). Two days before the experiment started, mussels were placed individually in hanging baskets in filtered (Millipore, 0.3 μm) seawater (32 PSU, 12 °C) for adaptation to the experimental setup, in which it was necessary to mix the water by magnetic stirring. The water (eight mussels in 15 L) was exchanged daily. It was continuously oxygenated, and the mussels were fed the nanoflagellate *Isochrysis galbana*. One hour before the start of the experiment, each basket with one mussel was transferred to a beaker with 700 mL filtered (Millipore, 0.3 m) and oxygenated seawater (32 PSU, 12 °C). The beaker was placed on the magnetic stirrer in front of the gamma camera. Ten minutes before addition of bacteria, the mussel was given 1 mL of a suspension of 10^6 mL^{-1} of *I. galbana* as a trigger for filtration, and the activity was visually confirmed. Thereafter, the radiolabeled microspheres and/or bacteria were added to the beaker. The final concentration of bacteria was approximately 3 10^6 mL^{-1}, and approximately 32.4 MBq of $^{99}Tc^m$ activity was added to the water. The concentration of the microspheres was approximately 1.5 10^6 mL^{-1}, and the activity of ^{113}Sn was approximately 1.1 MBq. All values used in this study have been corrected for the half-life of the isotopes.

Sixteen mussels were given *S. typhimurium* labeled in the presence of 80 μg SnF_2 (designated $^{99}Tc^m$:80), and 16 mussels were given *S. typhimurium* labeled in the presence of 800 μg SnF_2 (designated $^{99}Tc^m$:800). Within each group of mussels, 50% were given ^{113}Sn-labeled microspheres (NEN TRAC microspheres, Du Pont) together with the bacteria. The nondegradable microspheres were made from styrene-divinyl benzene resins and were uniform in size (15 μm) (designated ^{113}Sn:ms).

Each mussel was exposed to radiolabeled microbes/microspheres for 5 hours. During this time the radioactivity was continuously recorded by the gamma camera. Then the mussel was carefully rinsed and repositioned in front of the camera, but now in clean seawater for recording of elimination of radioactivity. Finally, the mussel was dissected and the radioactivity of the organs and tissue fractions was measured using a well-shielded NaI(Tl) detector (15 cm in diameter; Nuclear Enterprises, UK) in a low-activity laboratory. The dissected fractions were the fimbriae part of the mantle, one pair of gills, one pair of palps, pericardial gland including the pericardium, gonad, one pair of kidneys, digestive

gland, terminal part of intestine, crystalline style, mantle, posterior adductor muscle, foot, anterior adductor muscle, and retractor muscle. The digestive gland was transected to distinguish the anterior part, including the esophagus, stomach, and diverticular folds (designated the stomach) from the posterior part, including the direct and recurrent intestine and the blind sac (designated the liver). The terminal intestine (designated the gut) was dissected separately. The dissected part of the kidneys was one of the longitudinal canals that lie on either side of the body at the root of the gills and the closest connected tissue (designated the renal). As the transit time of the radioactive particles in the mussel tissue was unknown, the dissection was done with different time lags, and these were randomized among the mussels. Meanwhile, the mussels were stored as under the pre-experimental conditions, with a daily exchange of water but without any food supply. The time lags were 5, 20, 28, and 54 hours for the mussels fed on $^{99}Tc^{m}$:80 ($n = 4$ in each group). The mussels fed on $^{99}Tc^{m}$:800 were dissected after 5 ($n = 4$), 20 ($n = 4$), 28 ($n = 2$), 54 ($n = 2$), and 68 ($n = 4$) hours. It should be pointed out that these differences in numbers of mussel dissected at different times were not planned but were a result of the time-consuming dissection.

Gamma Camera Technique

The gamma camera technique (MAXI II General Electric, Hermes System NuD, Nuclear Diagnostic, Hägersten, Sweden) was used. The camera continuously visualizes the distribution of radioactivity in the mussel. Furthermore, by outlining the regions of interest (ROIs) on the screen, the radioactivity in the region was quantified and listed and displayed as curves of activity versus time. The ROIs chosen in this study were the images of the stomach and gut regions. The parameters were calculated from the stomach region as follows:

Uptake = the fraction (%) of the initial amount of the given radioactivity that was accumulated when the maximum value in the ROI was reached. The initial radioactivity in the beaker represented the given activity. The maximum value was normalized to the initial radioactivity to avoid differences due to variations in the given activity, differences due to the distance between the mussel and the camera, and differences in the geometry of the mussels.

Elimination = the reduction (%) from the maximum value measured in the ROI. The reduction was determined after 20 hours of measurement. These values were normalized to the maximum value in the ROI to avoid differences in the uptake capacity.

Statistical Analysis

The influence on the uptake and the elimination of the bacteria due to the chemical treatments (80 or 800 μg SnF_2) and to the presence or absence of ^{113}Sn:ms was analyzed using two-way analysis of variance (ANOVA) and a Tukey test to allow multiple comparisons (Zar 1995). The variance of the uptake and elimination of $^{99}Tc^{m}$:80, $^{99}Tc^{m}$:800, and ^{113}Sn:ms was analyzed using one-way ANOVA and a Tukey test (Zar 1995). To obtain independent measurements for the ANOVA analysis, the $^{99}Tc^{m}$:80 and $^{99}Tc^{m}$:800 groups included mussels fed exclusively on bacteria, and the ^{113}Sn:ms group included the same numbers of individuals randomized from the mussels fed simultaneously on bacteria and microspheres.

Because of the differences between $^{99}Tc^{m}$:80 and $^{99}Tc^{m}$:800 in time lags before dissection, some of the mussels were excluded to equalize the groups when analyzing the distribution of the microbes in the mussel tissue. The excluded mussels were the four fed on $^{99}Tc^{m}$:800 dissected after 68 h and two mussels randomly chosen among those fed on $^{99}Tc^{m}$:80 dissected after 28 and 54 h, respectively. The Mann-Whitney rank sum test (Sokal & Rohlf 1995) was used to compare variances in content of radioactivity in the different fractions. Pearson product moment correlation (Snedecor & Cochran 1989) was used to investigate whether an increased amount of radioactivity in mussel tissue outside the digestive tract was related to a decrease in the digestive gland. In all of the statistical analyses, Sigma Stat version 2.0 (Jandel Scientific Software, San Rafael, CA) was used.

RESULTS

Viability of ^{99m}Tc-Labeled Bacteria

The viability of the unlabeled bacteria was 96.4 ± 1.4%. The viability of $^{99}Tc^{m}$:80 was 95.9 ± 1.7%, and for $^{99}Tc^{m}$:800 it was 89.6 ± 4.2%. The microscopic inspections showed the same size and shape of the bacteria compared with the unlabeled bacteria, and no aggregates were observed.

Uptake and Elimination of Radiolabeled Bacteria and Microspheres in M. edulis

When mussels were given *S. typhimurium* labeled with a small amount of stannous fluoride ($^{99}Tc^{m}$:80; Fig. 1A), as well as radioactive microspheres (^{113}Sn:ms; Fig. 1B), the uptake of bacteria in the stomach was slow and small and in the gut it was nearly inconspicuous, whereas the microspheres rapidly accumulated in the stomach and later in the gut. The uptake when $^{99}Tc^{m}$:80 was tested alone (Fig. 1C) was similar to that of the bacteria in the mixture (Fig. 1A). Mussels given bacteria labeled with more stannous fluoride ($^{99}Tc^{m}$:800; Fig. 2A) as well as ^{113}Sn:ms (Fig. 2B) showed similar uptake kinetics for the two kinds of particles. A similar pattern appeared for $^{99}Tc^{m}$:800 alone (Fig. 2C).

Two-way ANOVA confirmed that the presence of the ^{113}Sn:ms affected neither the uptake nor the elimination of $^{99}Tc^{m}$:80 and $^{99}Tc^{m}$:800, but the difference due to the amount of stannous fluoride used for the labeling of the bacteria was significant (Table 1). The uptake (Fig. 3) and elimination (Fig. 4) varied on an individual basis. Still, the statistical analysis showed that the variances in the processing of $^{99}Tc^{m}$:80 compared with $^{99}Tc^{m}$:800 and ^{113}Sn:ms were significant. The uptake of ^{113}Sn:ms and of $^{99}Tc^{m}$:800 was significantly higher than that of $^{99}Tc^{m}$:80 [one-way ANOVA, $F = 32.4$; degrees of freedom (df) between subjects = 7; $P < 0.001$, post hoc Tukey test]. Similarly, the elimination of ^{113}Sn:ms and of $^{99}Tc^{m}$:800 was significantly higher compared with that of $^{99}Tc^{m}$:80 (one-way ANOVA, $F = 20.8$, df between subjects = 5; $P < 0.001$, post hoc Tukey test).

The Distribution of Radioactivity in M. edulis

The radioactivity in the different organs and tissues showed great differences between individuals. Despite this, the differences between the three different groups ($^{99}Tc^{m}$:80, $^{99}Tc^{m}$:800, and ^{113}Sn:ms) were pronounced. Most of the activity of ^{113}Sn:ms in the digestive tract (Fig. 5) was recovered in the stomach, in the liver, and in the gut. The activities of $^{99}Tc^{m}$:80 and $^{99}Tc^{m}$:800 were even higher in the stomach and liver. $^{99}Tc^{m}$:80 could hardly be detected in the gut. The gills contained significantly more

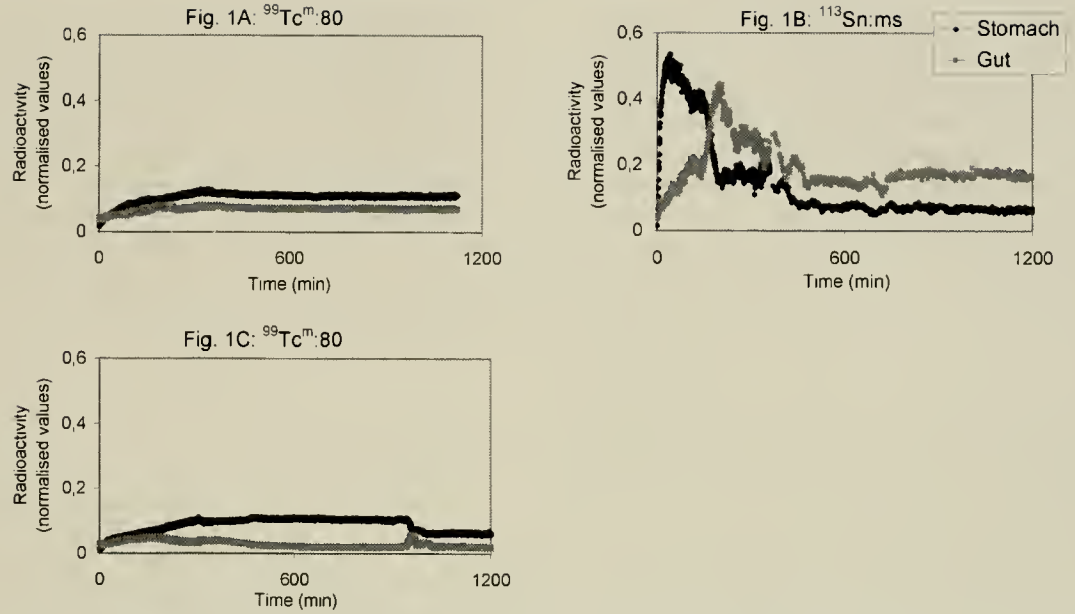

Figure 1. Chart lines showing the radioactivity measured in the ROIs (stomach and gut) in a mussel which was simultaneously given *S. typhimurium* labeled with $^{99}Tc^{m}$ in the presence of 80 µg SnF_2 ((A) $^{99}Tc^{m}$:80) and microspheres labeled with ^{113}Sn ((B) ^{113}Sn:ms). (C) Shows a mussel which was given $^{99}Tc^{m}$:80 only. The amount of radioactivity is normalized to the initial amount given to the mussel.

$^{99}Tc^{m}$:80 than $^{99}Tc^{m}$:800 (ANOVA, df = 15, $P = 0.028$). There were low values of $^{99}Tc^{m}$, and ^{113}Sn:ms were almost undetectable in the mussel tissue outside the digestive tract. When analyzing fractions with detectable activity, the gonad, posterior adductor muscle, mantle, and renal showed significantly (Mann-Whitney rank sum test) higher activities of $^{99}Tc^{m}$:80 than of $^{99}Tc^{m}$:800 (Table 2). The correlation analysis (Table 3) showed that when the amount of $^{99}Tc^{m}$:80 in the digestive gland decreased, the amount in gonad, adductor muscle, mantle, and renal increased. This was not the case when comparing the corresponding values for $^{99}Tc^{m}$:800.

The Transit Time of $^{99}Tc^{m}$ in M. edulis

The number of mussels dissected at 5, 20, 28, and 54 h were too few for any statistical ANOVA of transit time, but the general

Figure 2. patterns based on the mean values in Figure 6 gave some indications. In the posterior adductor muscle and the mantle, there was a reduction of radioactivity from $^{99}Tc^{m}$:80 and $^{99}Tc^{m}$:800 after 28 h. The most rapid accumulation and the highest values were measured in the gonads of the mussels fed $^{99}Tc^{m}$:80. The amount of $^{99}Tc^{m}$:80 did not decrease in the gonad and the renal during 54 h. The mussels fed on $^{99}Tc^{m}$:800 did not show any reduction in the renal after 68 h (Fig. 6). In the digestive tract, there was also detectable activity after 54 h. In the digestive gland, there was 0.45 ± 0.26 MBq × g^{-1} for $^{99}Tc^{m}$:80 and 0.57 ± 0.03 MBq × g^{-1} for $^{99}Tc^{m}$:800. In the gills, there was 0.16 ± 0.06 MBq × g^{-1} from $^{99}Tc^{m}$:80 but not detectable values from $^{99}Tc^{m}$:800.

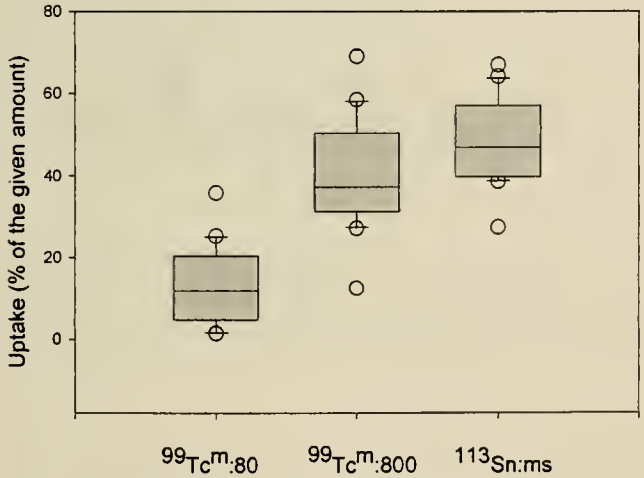

Figure 3. The uptake of radioactivity in the stomach (% of the given amount) when its maximum activity was measured, in 16 mussels fed on *S. typhimurium* labeled with $^{99}Tc^{m}$ in the presence of 80 and 800 µg SnF_2, respectively (^{99m}Tc:80 and ^{99m}Tc:800) and the microspheres labeled with ^{113}Sn (^{113}Sn:ms). Box plots display the median of the data, the lower and upper quartiles, and the lowest and highest values observed.

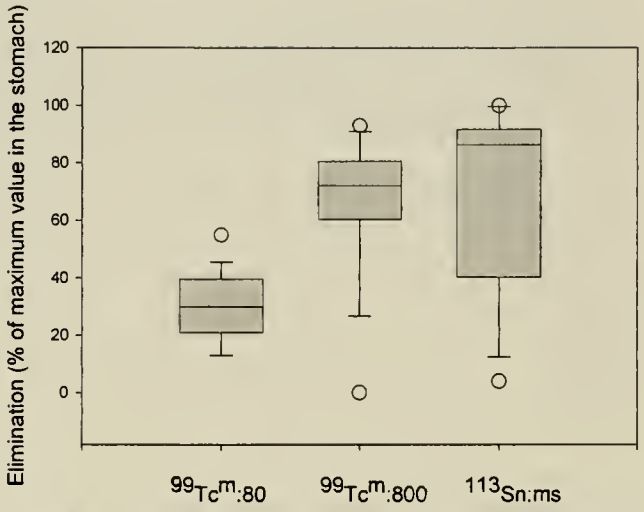

Figure 4. The elimination of radioactivity (% of the maximum value in stomach) determined 20 h after the experiment started, in 12 mussels fed on *S. typhimurium* labeled with $^{99}Tc^{m}$ in the presence of 80 and 800 µg SnF_2, respectively (^{99m}Tc:80 and ^{99m}Tc:800) and the microspheres labeled with ^{113}Sn (^{113}Sn:ms). Box plots display the median of the data, the lower and upper quartiles, and the lowest and highest values observed.

DISCUSSION

S. typhimurium 395 M R10 is an Rd-mutant deficient of the 0-antigenic polysaccharide side chain and with a pronounced negative surface charge (Edebo et al. 1980). Hernroth et al. (2000) described the chemical manipulation of *S. typhimurium*, using stannous fluoride. The electrophoretic mobility toward a cathode was significantly reduced for $^{99}Tc^{m}$:800 when compared with $^{99}Tc^{m}$:80 and untreated bacteria. In this study we have found differences in the mussel processing of the differently manipulated bacteria.

The preingestive selection of particles is expected to take place on the gills or on the labial palps. The structure of the gills is known to divert particles due to size (Riisgård et al. 1996), and it

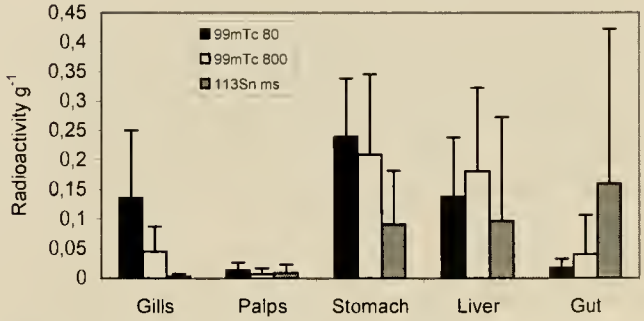

Figure 5. Distribution of radioactivity of *S. typhimurium* (+ standard deviation) labeled with $^{99}Tc^{m}$ in the presence of 80 and 800 µg SnF_2, respectively (^{99m}Tc:80 and ^{99m}Tc:800) and microspheres labeled with ^{113}Sn (^{113}Sn:ms), in the digestive tract [gills, labial palps, posterior part of the digestive gland (stomach) and the anterior part (liver) and terminal intestine (gut)]. The columns are based on the mean values (per g tissue) from 12 mussels dissected within 54 h.

TABLE 2.

Mann-Whitney rank sum test: comparison of median values ($^{99}Tc^m \times mg^{-1}$) in posterior adductor muscle, mantle, gonad, and renal from mussels fed on *S. typhimurium*, labeled in the presence of 80 and 800 µg of SnF_2, respectively.

Group	*n*	Median	25%	75%	$P < 0.05$
Adductor:80	12	0.99	0.47	2.35	
Adductor:800	12	0.29	0.15	0.55	Yes
Mantle:80	12	4.67	1.53	6.23	
Mantle:800	12	1.58	0.37	2.61	Yes
Gonad:80	12	1.5	0.85	3.22	
Gonad:800	12	0.63	0.12	1.00	Yes
Renal:80	12	42.5	27.5	59.5	
Renal:800	12	17.4	5.36	30.1	Yes

has been suggested that potentially nutritive particles will be selected relative to inert particles on the labial palps (Hylleberg & Gallucci 1975, Newell & Jordan 1983, Bayne et al. 1993). The uptake of $^{99}Tc^m$:800 and ^{113}Sn:ms was similar and much faster than that of $^{99}Tc^m$:80, showing that the size alone did not determine the uptake, because the $^{99}Tc^m$-labeled bacteria were much smaller (approximately 1µm) than the microspheres (15 µm). The higher uptake capacity of $^{99}Tc^m$:800 was correlated to a decrease of the net negative cell surface charge, indicating that negative charge might antagonize uptake. This study showed discrimination in ingestion of the less manipulated bacteria, and significantly more bacteria of this kind were "trapped" on the gills. A proper explanation to this requires further studies, and we suggest that it should include electrostatic repulsion and also hemocytic attachment or engulfment of bacteria on the gills.

The elimination of the bacteria was also affected by the chemical modification of the cell surface. The elimination was significantly lower for $^{99}Tc^m$:80 than that for $^{99}Tc^m$:800 which again was similar to that of ^{113}Sn:ms. The less-modified bacteria were to a high degree accumulated in the stomach part of the digestive gland, but were hardly present in the gut. According to Birkbeck and MacHenery (1982), this indicates a postingestive selection based on phagocytic activity. These authors showed, in their study of *M. edulis*, that the processing of bacteria after phagocytic uptake in the hepatopancreas digested the bacteria into polymers that were

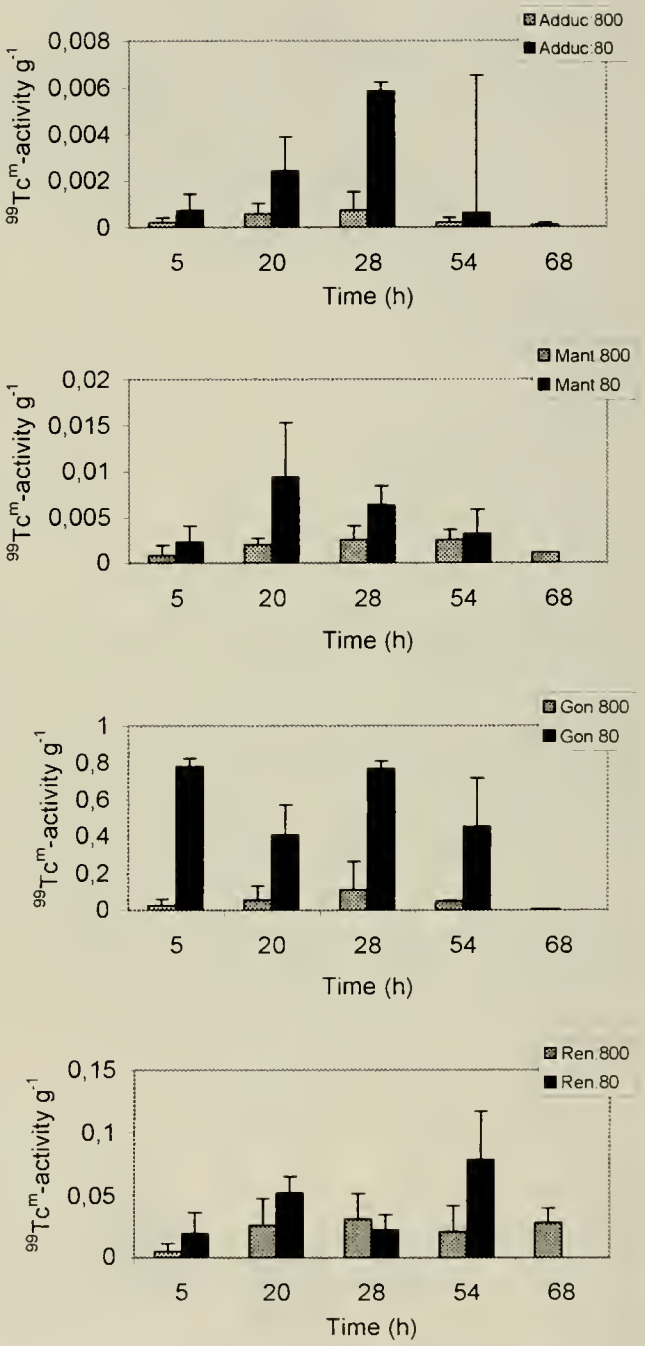

Figure. 6. Distribution of radioactivity of *S. typhimurium* labeled with $^{99}Tc^m$ in the presence of 80 and 800 µg SnF_2, respectively ($^{99}Tc^m$:80 and $^{99}Tc^m$:800) in posterior adductor muscle (Adduc), mantle (Mant), gonad (Gon), and renal (Ren) (NB: different scales). The columns are based on the mean values (per g tissue) from mussels dissected after 5, 20, 28, 54, and 68 h.

transferred to other sites in the mussel, whereas most of the lysozyme-resistant bacteria were rejected as fecal production. It has previously been shown that *M. edulis* can lyse bacteria extracellularly (Prieur 1981), but the slow processing and the preferential absorption of $^{99}Tc^m$:80 compared with $^{99}Tc^m$:800 that evidently occurred in our study indicated a predominance of phagocytosis and intracellular digestion of the less-manipulated bacteria. Absorption of radioactivity from $^{99}Tc^m$:80 was supported by the relationship between the decrease of radioactivity in the digestive

gland and the appearance in organs and tissue outside the digestive tract. This was not found for $^{99}Tc^{m}$:800. These bacteria were less absorbed and were more directly transferred into the intestine. The faster elimination with lower absorption efficiency shown for $^{99}Tc^{m}$:800 and ^{113}Sn:ms indicated extracellular digestion.

Radioactivity was still detectable in the digestive tract of the mussels dissected after 54 hours. This observation was made in a closed system in which the water was exchanged only on a daily basis and should not be compared with the depuration study of Martinez-Manzanares et al. (1992). They showed a rather rapid elimination of *Salmonella* spp. after purification in running seawater. However, Plusquellec et al. (1994) managed to detect *Salmonella* spp. in air-stored mussels, 20 days after contamination. Minet et al. (1995) found culturable cells of *S. typhimurium* in the gut 1 week after contamination. The possibility for extracellular survival of *S. typhimurium* in the digestive tract, including the gills, as indicated by the presence of radioactivity after 54 hours, needs further investigation. Extracellular survival can thus be a cause for shellfish-borne gastrointestinal infections and should be included in risk assessment. Likewise, we found ^{99m}Tc distributed in mussel tissue outside the digestive tract, such as gonads, kidney, mantle, and adductor muscle, 1-2 days after exposure to the bacteria. This might be caused by degraded bacteria but might also be an effect of resistance to phagocytosis and killing.

In the previous study by Hernroth et al. (2000), the stability of the isotope bindings to *S. typhimurium* in seawater was not significantly different for $^{99}Tc^{m}$:80 and $^{99}Tc^{m}$:800. Fragile binding could increase the amount of hydrolysed, reduced technetium or free pertechnetate, but these radiochemical impurities did not influence the uptake capacity of $^{99}Tc^{m}$ in the mussel. The possibility of diffusion of released $^{99}Tc^{m}$ into the mussel tissue could, as pointed out, interact with the measurement of the distribution of radioactivity in the mussel tissue. However, as the binding stability of $^{99}Tc^{m}$ was comparable for $^{99}Tc^{m}$:80 and $^{99}Tc^{m}$:800, this could not explain the differences in the distribution of these microbes shown in this study.

The viability estimated with the fluorescent probe of the labeled *S. typhimurium* was initially good (96% for $^{99}Tc^{m}$:80 and 90% for $^{99}Tc^{m}$:800), and the microscopic inspections confirmed intact cell size and shape and no aggregates. Thus, it was considered that the same numbers of viable $^{99}Tc^{m}$:80 and $^{99}Tc^{m}$:800 were given to the mussels. The differences in the uptake between $^{99}Tc^{m}$:80 and $^{99}Tc^{m}$:800 occurred directly from start, indicating that viability was not the discriminating factor for uptake.

This investigation has shown that the uptake, distribution, and elimination of microbes by the blue mussel are strongly influenced by the cell surface characteristics of the microbe. This factor might be at least as important as particle size. We suggest that recognition for phagocytic uptake might play an important role in the processing of microbes.

ACKNOWLEDGMENTS

We thank Prof. Magne Alpsten for providing us with the gamma camera facilities; Britta Ahlström, MD, for valuable advice concerning the culturing of bacteria; and Ann-Sofi Rehnstam-Holm, PhD, for discussing the manuscript. This research was supported in part by the Adlerberth Foundation and by the Sustainable Coastal Zone Management within the Foundation for Strategic Environmental Research.

ABSTRACT This paper presents a radiolabeling method for *Salmonella typhimurium* to be used for *in vivo* studies on the kinetics of uptake in blue mussels with a gamma camera technique. *S. typhimurium* bacteria were labeled with technetium-99m ($^{99}Tc^{m}$) at conditions preserving the viability in seawater and the cell surface properties of the bacteria. Stannous fluoride (SnF_2) was used to facilitate the binding of $^{99}Tc^{m}$ to the bacteria. The toxicity of SnF_2 could inhibit the growth of bacteria, and it can also bind extracellularly and reduce the negative cell surface charge of the bacteria. Additionally, SnF_2 can cause radiochemical by-products such as Tc-stannous colloids, which might interact with the image analysis. To optimize the labeling, two different concentrations of SnF_2 used in the labeling process were evaluated. Neither the efficiency nor the stability of the binding of $^{99}Tc^{m}$ to the bacteria increased significantly, when the amount of SnF_2 was increased 10-fold. Both treatments of bacteria reduced the viable counts, whereas the viability assessed microscopically with fluorescent probe was affected only little. However, after incubation in seawater, the viability was reduced for cells treated with the highest concentration of SnF_2. Still, approximately 60% remained viable. Presence of radioactivity, not bound to bacteria, was investigated by centrifugation in Percoll. Less than 4% of probable Tc-stannous colloids were found, and they were therefore not considered to be disturbing the imaging analysis. The net negative surface charge of the bacteria, examined by measuring the electrophoretic mobility, was significantly reduced when the concentration of SnF_2 increased, but was still negative. Radioactive particles, formed by mixing $^{99}Tc^{m}$ and SnF_2 in the absence of bacteria, were rapidly taken up by mussels in a way similar to that of the more heavily labeled bacteria. When less SnF_2 was used for labeling of the bacteria, different uptake and processing kinetics were seen. Thus, to keep the natural conditions, the concentration of the labeling compounds have to be minimized. The study showed that it is possible to balance the labeling method and get a valuable tool for following the uptake and fate of *S. typhimurium* in blue mussels.

KEY WORDS: Gamma camera, radiolabeling, 99m-technetium, ^{99m}Tc, *Salmonella typhimurium*, bacteria, *Mytilus edulis*, bivalves, molluscs, uptake, elimination, enteric infections

INTRODUCTION

The blue mussel, *Mytilus edulis*, is in nature exposed to a mixture of particles and is able to accumulate high numbers of microbes from the surrounding water. The potential for the mussel to become a carrier of food-borne diseases is therefore significant, and several reports have pointed out the molluscs as commonly incriminated in outbreaks of enteric infections (West et al. 1985, Martinez-Manzanares et al. 1992, Wittman and Flick 1995, Ripabelli et al. 1999). Depuration studies on bivalves have shown great individual variations between mussels (Heffernan and Cabelli 1971, Plusquellec et al. 1994) and variations due to bacteria species (Plusquellec et al. 1998). This stresses the necessity of studies on the uptake and elimination of microorganisms in individual bivalves to establish satisfying monitoring programs and to improve risk assessment with respect to public health.

Gamma-emitting radionuclides in bacteria can be used for *in vivo* imaging distribution. Technetium-99m ($^{99}Tc^{m}$) isotope has been used as a radiotracer when studying phagocytosis of viable bacteria in vertebrates (Plotkowski et al. 1987, Bernardo-Filha et al. 1991, Perin et al. 1997). In the coupling process, stannous fluoride (SnF_2) has been used to reduce $^{99}Tc^{m}$ from +VII to +IV, which facilitates its binding (Rhodes 1991, Perin et al. 1997). SnF_2 is also known for its bactericidal effect (Tsao et al. 1982, Caufield et al. 1987, Oosterwaal et al. 1989, Oosterwaal et al. 1991), and therefore the amount used in the labeling process has to be selected with care. SnF_2 acts as an inhibitor of glycolytic enzymes, as it binds to SH groups. The metal ions interact with both Gram-positive and Gram-negative bacteria, and the antimicrobial effect depends on the concentration of free ions as well as the chemistry of the ions in the specific system (Scheie 1994). In addition, the concentration of SnF_2 must be used with care, as it might influence the cell surface properties of the bacteria. Olsson and Oldham (1978) have proved that the binding of metal ions to bacteria alters their cell surface charge and adherence ability. With the amount of stannous fluoride used by Plotkowski et al. (1987) in the $^{99}Tc^{m}$ labeling of the *Pseudomonas aeruginosa*, the electrophoretic mobility was not changed, but Perin et al. (1997) showed that the $^{99}Tc^{m}$ labeling of *S. abortusovis* demands a higher concentration of SnF_2. As it has been shown that particle processing in *M. edulis* can be effected when the particles are enriched in metals (Wang et al. 1995, Al-

lison et al. 1998), the concentration of stannous in the labeling process is critical.

An indirect labeling method has been used to follow the distribution of leukocytes in humans (Mock and English 1987, Puncher and Blower 1995). In these assays, leukocytes were labeled intracellularly by phagocytosis of colloidal compounds of $^{99}Tc^{m}$ and SnF_2 (Tc-stannous colloid). These studies also demonstrated that active compounds might have occurred as nonspecific, cell surface-bound labeling with low affinity and soluble radiocolloids. Radiochemical by-products might also occur in the direct labeling of bacteria. As a side reaction, the reduced technetium can bind to more low-affinity binding sites or together with SnF_2 form Tc-stannous colloids. There is a possibility that released pertechnetate or Tc-stannous colloids might be ingested by the mussel and confuse the image analyses of the bacteria. Because of the complications described, the labeling method has to be optimized to avoid decreased viability of the bacteria and radiochemical impurities. Furthermore, alteration of the surface properties by the labeling process has to be taken into consideration, as this could affect the processing of the bacteria in *M. edulis*.

Salmonella can appear in the marine environment because of fecal contamination (Prazeres Rodrigues et al. 1989, Papapetropoulou & Moschopoulos 1996, Wilson & Moore 1996) and is of great interest in terms of shellfish safety. The aim of this study was to investigate and evaluate the $^{99}Tc^{m}$-labeled *Salmonella typhimurium* as a tool to study its uptake and fate in *M. edulis*. *S. typhimurium* 395 MR10 was chosen because it is nonvirulent and known to be well accessible to phygocytosis, killing, and degradation in mammalian systems (Edebo et al. 1980). Considering the evaluation of the method used in the direct labeling of *S. abortusovis* (Perin et al. 1997), we compared the effect of two different concentrations of SnF_2 on (1) the viability of labeled *S. typhimurium* in seawater, (2) the labeling efficiency of the bacteria and the stability of the label in seawater, (3) the formation of Tc-stannous colloids during the labeling process, (4) the cell surface charge of the labeled bacteria, and (5) interaction of the labeled bacteria with *M. edulis*.

MATERIALS AND METHODS

Bacterial strain and growth conditions

S. typhimurium 395 MR10 (chemotype Rd, deficient of *O*-antigenic polysaccharide side chain and most core sugars of the lipopolysaccharide) has been described by Edebo et al. (1980). A single bacterial colony was harvested from a nutrient agar plate (beef extract, Oxoid 10 g; peptone, Oxoid 10 g; NaCl 8 g; glucose 7.5 g; and agar 1.4%) and cultured in glucose broth, pH 7.0-7.2 (Lindberg et al. 1970) at 37 °C on a rotary shaker (200 rpm) for 16 h. The bacteria were washed three times by centrifugation (2000 rpm, 10 min, 4 °C) in 0.9% NaCl and resuspended in 2 mL 0.9% NaCl (2.5×10^9 mL^{-1}). With these culturing conditions, the bacteria are considered to reach the prestationary phase.

Radiolabeling of bacteria

One milliliter of the bacterial suspension (2.5×10^9 mL^{-1}) was incubated with approximately 50 MBq $^{99}Tc^{m}$-pertechnetate and 2 mL of 37 °C 0.9% NaCl containing 80 and 800 μg SnF_2, respectively, to cause reduction of $^{99}Tc^{m}$. After incubation for 20 min at 37 °C on a rotary shaker (200 rpm), the bacteria were centrifuged and washed three times. Ascorbic acid (0.25 mg × mL^{-1}) was added to the NaCl to prevent reoxidation of the isotope (Rhodes 1991). The bacteria were resuspended in 1 mL 0.9% NaCl.

Bacterial viability

For estimation of the effect of the labeling procedure on the viability, bacteria treated with $^{99}Tc^{m}$-pertechnetate as well as with 80 (n = 6) or 800 (n = 6) μg SnF_2, respectively, were compared with control bacteria incubated in 2 mL 0.9% NaCl (n = 6) only. The suspensions of bacteria were serially diluted in phosphate-buffered saline (NaCl 0.15 M, sodium phosphate 0.01 M, pH 7.2 7.4), spread onto nutrient agar plates using a spiral plating system (Spiral System Inc., Cincinnati, OH), incubated at 37 °C for 24-48 h, and the colonies counted and the colony-forming units per mL (CFUs × mL^{-1}) calculated.

The viability of the bacteria was also investigated using the LIVE/DEAD® *Bac*Light™ Bacterial Viability Kit (Molecular Probes, The Netherlands). Live bacteria appear with green fluorescence (SYTO 9), whereas the red fluorescence of membrane-impermeant propidium iodide dominates membrane-compromised bacteria (Haugland 1996). The bacterial suspensions were diluted ($5 \times 10^6 \times mL^{-1}$) in sterile filtered (Schleicher & Schuell, Keene, NH; FP 030/3) seawater (33.69 PSU, 6 °C), incubated on a rotary shaker (200 rpm) with the fluorescent probe for 15 and 180 min, observed in an epifluorescence microscope (Zeiss Axioscop, excitation filter BP450-490, dichroic reflector 510, barrier filter LP5159, Zeiss, Germany), and the fraction of viable cells calculated. After all labeling processes, the bacterial suspensions were observed in a light microscope (12.5 × 100 times magnification) to check possible effects on shape and size and aggregate formation.

Efficiency and stability of the $^{99}Tc^{m}$ labeling

After the labeling process, the radioactivity of $^{99}Tc^{m}$-labeled bacteria was measured using a well-shielded NaI(Tl) detector (15 cm[diameter]; Nuclear Enterprises, UK) in a low-activity laboratory. The labeling efficiency was expressed as percentage of the initial activity bound.

The stability of the binding was tested by incubation of three batches of bacteria (final concentration $5 \times 10^6 \times mL^{-1}$), labeled in the presence of 80 and 800 μg SnF_2 respectively, in filtered (Millipore 0.3 μm) seawater (33.69 PSU, 6 °C). Triplicate samples were taken within 3 min and then after 15, 30, 60, and 180 min. Particles >0.2 μm were separated from the water using sterile filters (Schleicher & Schuell; FP 030/3), and the filtered volume was collected in vials and the fractions were measured in the well-shielded NaI(Tl) detector. The bounded part was expressed as the particulate fraction of the total radioactivity.

Radiochemical by-products

Possible formation of Tc-stannous colloids in the labeling solution was investigated by separation in Percoll (n = 3), with a density of $1.12 \text{ g} \times mL^{-1}$. One milliliter of the labeled bacteria was layered on the Percoll, and the tubes were centrifuged for 20 min at 2000 rpm. Free $^{99}Tc^{m}$-pertechnetate and two colloidal suspensions were used as references. The colloidal suspensions were formed when $^{99}Tc^{m}$ was incubated in the presence of 80 and 800 μg SnF_2, respectively, without bacteria (in this paper called Tc+80 and Tc+800). After centrifugation, the tubes were placed in front of the gamma camera and the separated parts were measured and calculated as a percentage of the total radioactivity.

Cell microelectrophoresis

The cell surface charge of the bacteria, labeled in the presence of 80 and 800 μg SnF_2, respectively, was investigated using microelectrophoresis (Mark II, Rank Brothers Ltd., Cambridge, England). The electrophoretic mobility ($m^{-2} \times V^{-1}s^{-1}$) of the chemically treated bacteria was compared with that of untreated bacteria. The bacteria were diluted in 5 mM KCl, and the time needed to pass a 180-μm grid in the electric field (90 V; distance between electrodes, 64.6 cm) was measured 10 times. The variances between the treatments were analyzed using one-way analysis of variance on ranks (Student-Newman-Keuls method) (Sokal & Rolph 1969).

Uptake by M. edulis of radiolabeled bacteria and possible by-products

Mussels were kept in circulating seawater of approximately 33 PSU at 6 °C and fed the nanoflagellate *Isochrysis galbana* before the experiment started. The mean length of the mussels was 7.1 ± 0.5 cm, and the mean wet flesh weight was 9.1 ± 3.0 g. Two sets of two mussels each were used to study the uptake of *S. typhimurium* labeled in the presence of 80 μg SnF_2 (S:80) and in the presence of 800 μg SnF_2 (S:800). As control mussels, two were given the colloidal suspension (without bacteria) incubated with $^{99}Tc^m$ and 80 μg SnF_2 (Tc+80), two mussels were given the suspension incubated with $^{99}Tc^m$ and 800 μg SnF_2 (Tc+800), and two mussels were given a suspension with free $^{99}Tc^m$-pertechnetate (free Tc).

Single mussels were positioned in front of the gamma camera, and hung above the bottom in beakers containing approximately 700 mL of filtered (Millipore 0.3 μm) seawater (33.7 PSU). The water was kept at 6 °C, well mixed with a stirrer, and oxygenated during the experiment. Labeled bacteria or reference solutions were added to the beaker. The final concentration when given the bacteria was approximately 5×10^6 mL^{-1}. The distribution of radioactivity was visualized for 5 h using a conventional, computer-aided gamma camera technique (MAXI II, General Electric; Hermes-system NuD, Nuclear Diagnostic, Hägersten Sweden) as shown in Figure 1. By outlining the region of interest (ROI) of the image, the amount of radioactivity in the chosen region was measured. The ROI chosen for this study was the area where the radioactivity was accumulated after passing the gills, identified as the stomach. The uptake was estimated as the accumulated fraction of the given amount of radioactivity (%), measured when the maximum value in the ROI was reached and the uptake rate was calculated (% min^{-1}). The values were normalized to the initial amount of radioactivity to eliminate differences in the given amount of activity and geometric properties, such as mussel size and shape and the distance between the mussel and the camera. The radioactivity was corrected for the half-life of the isotope (6 h).

RESULTS

Viability of the ^{99m}Tc-labeled bacteria

Compared with the unlabeled bacteria, the viable counts on agar plates were significantly reduced for both S:80 and S:800. When analyzing the unlabeled bacteria, 187 ± 29 × 10^7 CFU were found. The CFUs for S:80 and S:800 were 33 ± 16 × 10^7 and 10 ± 2 × 10^7, respectively, corresponding to a reduction of 82 and 95%, compared with the control. The fluorescence assay showed (Fig. 2) that after incubation for 15 min in seawater, the viable

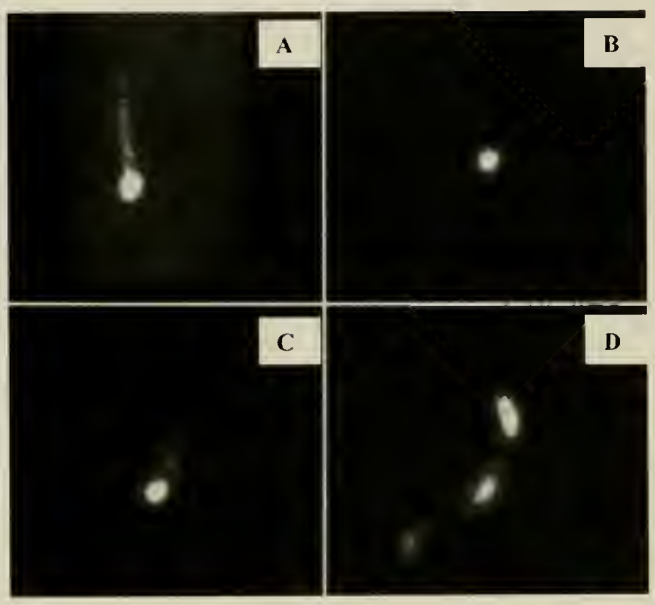

Figure 1. Gamma camera image of a mussel after being given bacteria labeled with $^{99}Tc^m$ in the presence of 800 μg SnF_2. (A) Concentrated along the gills of the mussel. (B) Accumulated in the stomach region. (C) Directed to the gut. (D) Transported as fecal content through the gut.

fraction of S:80 (88 ± 6%) was similar to that of the unlabeled bacteria (94 ± 2%). The corresponding value for S:800 was 81 ± 8%. After incubation for 180 min in seawater, the viable fractions of the unlabeled bacteria and S:80 remained unchanged, being 97.3 ± 0.6% for the unlabeled bacteria and 96.9 ± 2.2% for S:80, whereas for S:800 it was significantly reduced (59.2 ± 4.5%). The microscopic inspections showed that the cell size (approximately 1 μm) and shape were not altered for S:80 and S:800, and no aggregates were observed.

Efficiency and stability of the $^{99}Tc^m$ labeling

The efficiency of the labeling of S:80 (77 ± 7%) and of S:800 (70 ± 14%) was not significantly different. The amount of $^{99}Tc^m$ released during the first hour in seawater was approximately 37% for S:80 and 30% for S:800. During the following hour, the bound $^{99}Tc^m$ stayed more stable (Fig. 3).

Radiochemical by-products

After centrifugation in Percoll (Fig. 4), free Tc stayed on the top layer (96 ± 1%), as did the bacteria, S:80 (95 ± 2%), and S:800

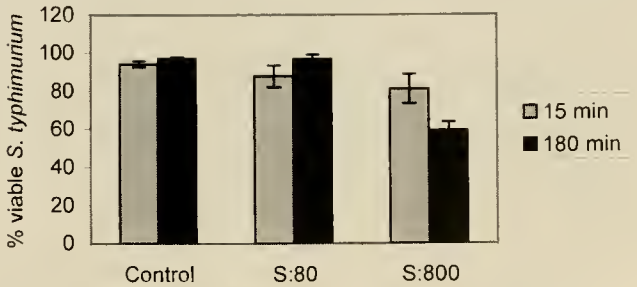

Figure 2. Viable cells (% of the total number of cells) (+SD, n=6), estimated by fluorescence assay, of *S. typhimurium* labeled in the presence of 80 (S:80) and 800 (S:800) μg SnF_2, respectively, and unlabeled *S. typhimurium* (Control). The viability was estimated after 15 and 180 min of incubation in seawater.

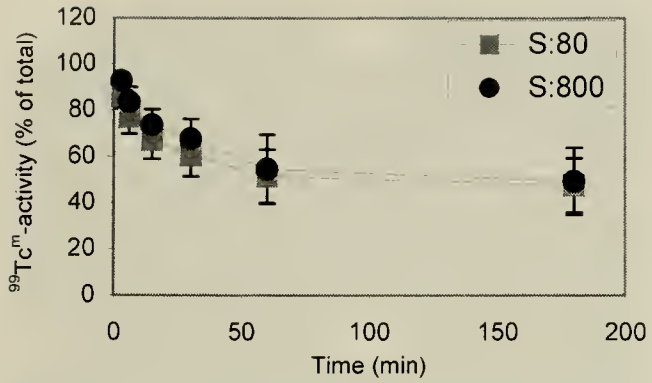

Figure 3. The particulate fraction (%) of the total amount of $^{99}Tc^{m}$ (+SD, n=9) from *S. typhimurium* labeled in the presence of 80 (S:80) and 800 (S:800) µg SnF_2, respectively, measured during 180 min of incubation in seawater.

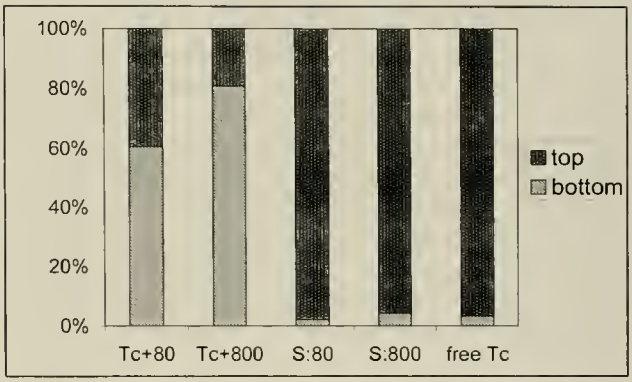

Figure 4. The mean percentage of the total amount of $^{99}Tc^{m}$ activity (n=3) accumulated in the top and the bottom layers of the test tube after centrifugation in Percoll. The columns show $^{99}Tc^{m}$ incubated only with 80 (Tc+80) and 800 (Tc+800) µg SnF_2, *S. typhimurium* labeled with $^{99}Tc^{m}$ in the presence of 80 (S:80) and 800 (S:800) µg SnF_2, and free $^{99}Tc^{m}$-pertechnetate (free Tc).

(92 ± 1%), and less than 4% were found at the bottom. In the tubes with colloids formed during the incubation of $^{99}Tc^{m}$ with SnF_2 (without bacteria), more were found at the bottom. The bottom fraction increased with the amount of SnF_2, showing 48 ± 17% of the radioactivity in Tc+80 and 71 ± 22% in Tc+800.

Cell microelectrophoresis

One-way analysis of variance on ranks (Kruskal-Wallis) showed that the electrophoretic mobility for *S. typhimurium* was affected by the treatments of the bacteria (Table 1). There was a statistically significant reduction in electrophoretic mobility for S:800 compared with S:80 and untreated bacteria. The median value for S:800 was 2.3×10^{-9} $m^2 \times V^{-1}s^{-1}$. For S:80 it was 5.4×10^{-9} $m^2 \times V^{-1}s^{-1}$ and for untreated bacteria 4.7×10^{-9} $m^2 \times V^{-1}s^{-1}$.

Uptake by M. edulis of radiolabeled bacteria and possible by-products

Preliminary studies on the uptake of labeled bacteria by mussels showed that initially the radioactivity accumulated in the gill area and subsequently in the stomach and gut region (Fig. 1). Figure 5 displays the curves from the measurements of radioactivity in the stomach from the two mussels given bacteria (S:80 and S:800, respectively). The accumulation of S:80 in the stomach region was 11 ± 1.4% of the given amount of radioactivity and the process was slow (0.04 ± 0.01% min^{-1}) and nondynamic. Of the given activity of S:800, 32.7 ± 0.28% was measured in the stomach. The accumulation was faster (0.36 ± 0.20% min^{-1}), and the reduction came in pulses.

Figure 6 displays the curves from the measurements of radioactivity in the stomach from the two mussels fed on the colloidal suspensions (Tc+80 and Tc+800, respectively). The radioactivity from Tc+80 was 21.2 ± 3.6%, and the uptake rate was 0.14 ± 0.01% min^{-1}. For Tc+800, the uptake was 31.1 ± 2.2% and the process was faster (0.31 ± 0.02% min^{-1}). The dynamic movements of the radioactivity in the stomach were similar between these mussels. The radioactivity from the two mussels given free Tc was below the limit of detection.

DISCUSSION

S. typhimurium 395 MR10, used in this study, is a deep rough (chemotype Rd) mutant (Edebo et al. 1980), its surface is more hydrophobic and negatively charged than in most other *Salmonella*, and it forms a homogenous single-cell suspension in water. Labeling with $^{99}Tc^{m}$ using the high amount of SnF_2 (S:800) reduced the net negative charge of the bacteria as studied by use of electrophoresis. When less SnF_2 (S:80) was used, no effect on charge was discerned. Wang et al. (1995) and Allison et al. (1998) have suggested that the cell surface properties of particles will influence the preingestive selection on the labial palps. Our results are in accordance with these suggestions. The reduced net negative charge of S:800 was probably a consequence of accumulation of

TABLE 1.

One-way ANOVA on ranks (Kruskal-Wallis) comparing the electrophoretic mobility ($m^2 \times V^{-1}s^{-1}$) for *S. typhimurium*, treated with 80 and 800 µg SnF_2, respectively (S:80, S:800), and untreated *S. typhimurium* (control) (post hoc Student-Newman-Keuls).

Group	*n*	Median	25%	75%
Control	10	4.7×10^{-9}	4.1×10^{-9}	5.1×10^{-9}
S:80	10	5.4×10^{-9}	4.7×10^{-9}	6.5×10^{-9}
S:800	10	2.3×10^{-9}	2.1×10^{-9}	2.5×10^{-9}

Comparison	Difference of Ranks	p	q	P < 0.05
S:800 vs. S:80	156	3	5.6	Yes
S:80 vs. control	24	2	1.28	No
Control vs. S:800	132	2	7.06	Yes

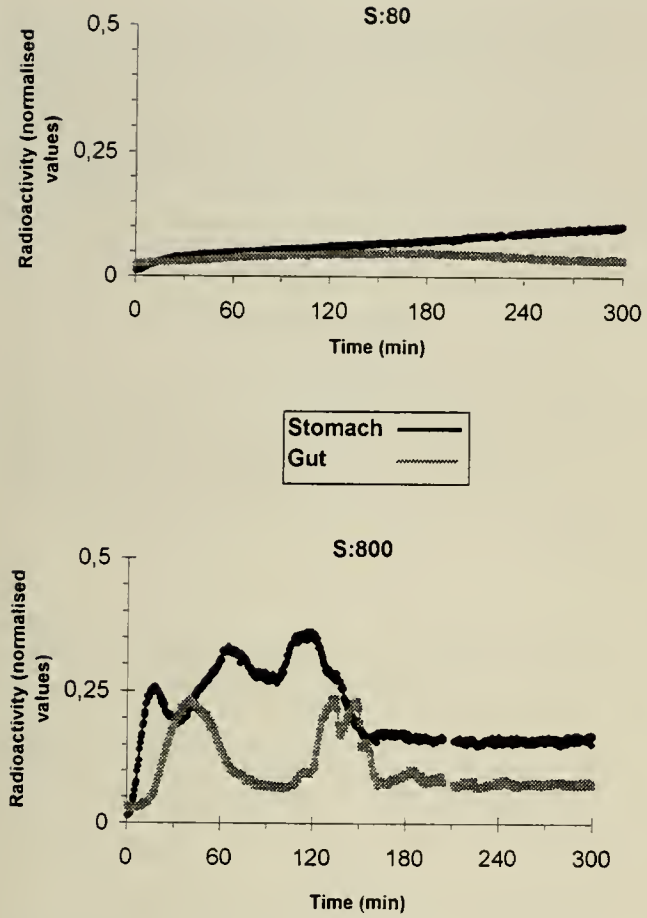

Figure 5. Curves showing the $^{99}Tc^{m}$ activity in the stomach and gut (observation time 5 h) of mussels fed *S. typhimurium*, labeled in the presence of 80 (S:80) and 800 (S:800) µg SnF_2.

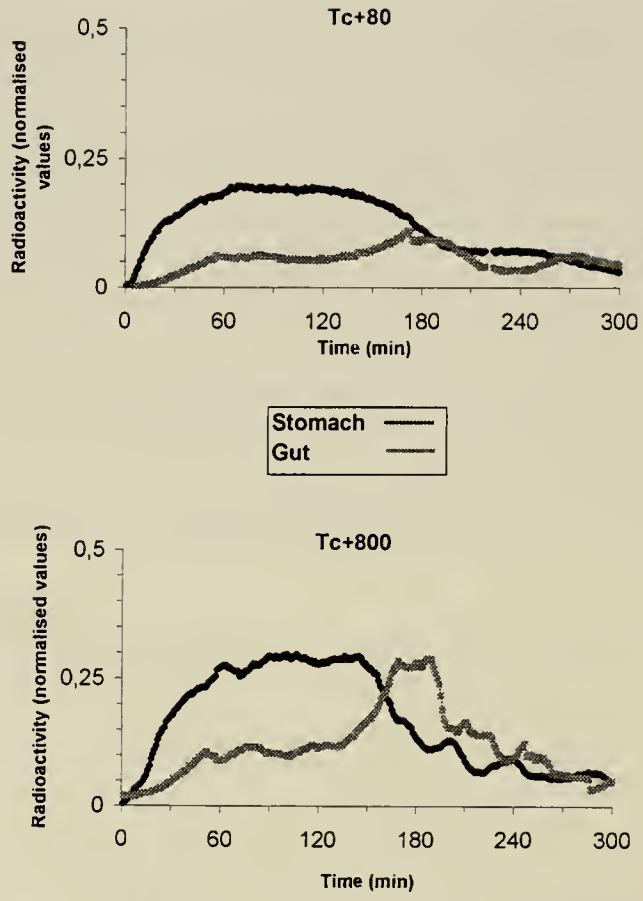

Figure 6. Curves showing the $^{99}Tc^{m}$ activity in the stomach and gut of mussels (observation time 5 h) given a suspension of by-products (probable $^{99}Tc^{m}$-stannous colloids) formed during incubation with the isotope and 80 µg SnF_2 (Tc+80) and the isotope and 800 (Tc+800) µg SnF_2.

positively charged metal complexes at its surface. These complexes might work as ligands for binding to mussel receptors or mainly operate by reducing the electrostatic repulsion between the bacterial particles and the recipient mussel surface. The differences in the cell surface properties between S:80 and S:800 might be a possible explanation for the differences shown in uptake and kinetic handling of the bacteria in the mussels.

Previous studies by Mayhew and Brown (1981) and Tseng and Wolff (1991) showed that SnF_2 inhibits the growth of the bacteria. This was also the case in our study. The viability in terms of viable counts was significantly reduced for S:80 and still more so for S:800. Bacteria in the prestationary phase were used for the labeling experiment, but log phase might have been a better condition for preserving the viability. However, the suppressed growth on agar did not correspond to the viability estimated by use of a fluorescent compound, probing the integrity of the barrier of the cell membrane, indicating that the labeling process may impair growth and division without conspicuously disturbing the cell membrane barrier. S:80 was better maintained during the incubation in seawater, but initially the viability of S:80 and S:800 was similar. Our evaluation is that the differences shown for the uptake should not be explained by differences in viability, since this phenomenon appeared directly from start when the viability of S:80 and S:800 was still comparable. The similarity between S:80 and S:800 in cell membrane integrity, size, and shape made us judge them as equal prey when given to the mussels.

According to Ross et al. (1984), the size of Tc-stannous colloids is approximately 1.5 µm, which is close to that of *S. typhimurium*. When giving the mussels the suspension with complexes formed between $^{99}Tc^{m}$ and SnF_2, without involvement of biological material, radioactivity was also accumulated in the mussels, in a way very similar to that of the more heavily labeled bacteria. These results indicate that the metal complexes on the surface of bacteria play a mediating role in the uptake process and that by-products formed when labeling the bacteria can influence the imaging analysis. The fraction of activity not bound to the bacteria was not greater than the fraction of by-products found when analyzing free pertechnetate, which indicates that it might include free or hydrolyzed pertechnetate and not only colloids. However, these fractions of "probable colloids" produced less than 4% of the total amount of radioactivity, and the influence on image analysis was considered to be of minor importance for the purpose of this study.

The amount of free or hydrolyzed pertechnetate in the bacterial suspension could not be established. The labeling efficiency was not significantly different comparing S:80 and S:800. The mean efficiency was 73.3%, and there is no evidence that the excess of $^{99}Tc^{m}$ was separated from the bacteria through the washing steps. In addition, a released fraction of radioactivity from the bacteria suspension appeared during the incubation in seawater. However, this study showed that even though the mussels were offered only

free pertechnetate (free Tc), the uptake was not detectable and did not affect the measurements. The possibility of passive diffusion of free pertechnetate cannot be excluded and needs further investigation.

The appearance of soluble $^{99}Tc^{m}$ was not significantly greater for S:800 than for S:80 after 180 min of incubation, even though the viability was more reduced. Thus, only a limited proportion of the bacteria were lysed, or lysed bacteria did not release the radiotracer. The feeding activity of the mussels can be stimulated both for particulate or nonparticulate food (Thompson and Bayne 1972). Cell leakage due to lysed bacteria could elicit a chemosensory response, which might explain the preferential uptake of S:800. However, the intact state of cell membranes and similar uptake of Tc-stannous colloids argue against such an effect. Aggregation of the bacteria would also affect the ingestion, but as no aggregates were found by the microscopic inspection, this explanation is rejected.

In summary, this study showed that there seems to be a higher uptake capacity and a more dynamic processing of the bacteria in the digestive gland due to the amount of SnF_2 used in the labeling process. The disturbance of the processing stresses the importance to keep the bacteria in a state as natural as possible. Although stannous fluoride is a toxic component to bacteria, it can be used as a reducing agent in the labeling process to produce a stable gamma-emitting bacterial tracer. However, the concentration used for this purpose has to be taken in consideration when studying uptake of viable bacteria in mussels. Bacteria labeled with gamma-emitting radionuclides, such as $^{99}Tc^{m}$-pertechnetate, have the potential to be used in numerous applications of bivalve research.

ACKNOWLEDGMENTS

We thank Assoc. Prof. Staffan Wall, Department of Physical Chemistry, Göteborg University, for helping us with the determination of the electrophoretic mobility of the bacteria. This study was funded through grants provided by Adlerberth Foundation and the Sustainable Coastal Zone Management (SUCOZOMA) project of the Foundation for Strategic Environmental Research (MISTRA).

ISOLATION AND CHARACTERISATION OF A cDNA ENCODING AN ACTIN PROTEIN FROM THE MUSSEL, *MYTILUS GALLOPROVINCIALIS*

GUILLAUME MITTA, PHILIPPE ROCH, AND JEAN-PAUL CADORET*
Défense et Résistance chez les Invertébrés Marins (DRIM) IFREMER-CNRS-Université de Montpellier II - Case courrier 80 – 2 Place Eugène Bataillon F-34095 Montpellier Cedex 05, France

ABSTRACT A full-length complementary DNA encoding an actin was isolated from a *Mytilus galloprovincialis* hemocyte library. This actin displays a typical 376 amino acid open reading frame. Northern blotting indicated that the expression of the actin gene is particularly abundant in muscular tissues. This actin cDNA will be useful as a potential genetic marker as a standard for expression level in genetic regulation studies and will allow screening for the whole gene as well as its upstream regulation sequences.

KEY WORDS: Actin, *Mytilus galloprovincialis*, mollusk

INTRODUCTION

Actins are highly conserved contractile proteins ubiquitous in all eukaryotic cells. In muscle cells it is important in myofibrillar contraction, and in non-muscular cells these proteins play a role in diverse functions such as motility, phagocytosis, chromosome movements, and transport of macromolecules within the cells (Korn 1978). Muscle-specific actins can be distinguished from cytoplasmic actin in vertebrates by their primary sequences (Vandekerckhove and Weber 1978). For example, the amino acid Val 10 is characteristic of cytoplasmic actin, while Val 17 is typical of muscular actin. Wesseling proposed 3 boxes in the N-terminal region as diagnostic for the family to which an actin belongs (Wesseling et al. 1988). In invertebrates, actins also have both muscular and non-muscular functions, but these two classes are not readily distinguished on the basis of amino acid sequence. Indeed, invertebrate muscular forms of actins are closer to β-cytoplasmic pattern of vertebrate. In practice, rigorous analysis of tissue expression is necessary in order to distinguish between the different forms. Actin genes are very abundant and constitutively expressed. As such they have been subject to numerous studies also among invertebrates (Gomez-Chiarri et al. 1994; Horard et al. 1994; Lardans et al. 1997; Cadoret et al. 1999).

The bivalves rely on an innate immune defence based on both cellular and humoral components which interplay to eliminate potentially infectious microorganisms. One such innate immune mechanism is the production of antimicrobial peptides which have been recently identified in mussels of the genus *Mytilus sp.* (Hubert et al. 1996; Charlet et al. 1996; Mitta et al. 1999a,b). A deeper knowledge of this defence system would allow the establishment of health controls to detect bivalve immunodeficiency, the selection for disease resistance with a coupling of immunology and genetics or by referring to classical genetics, the characterisation of immune genes could be exploited in genetic quantitative selection. Finally, genetic transformation constitutes another promising strategy to obtain resistant strains by various modifications systems. As part of this strategy, the identification of constitutive genes like the actin, that provide tools in the study of regulation mechanism of the identified peptides was undertaken. We isolated a full-length actin cDNA and carried out initial mapping of its expression by Northern blot experiments. This is a first step toward the identification of promoter regions as well as the sequencing of the whole gene.

MATERIAL AND METHODS

Animals and Hemolymph Collection

Adult mussels (*Mytilus galloprovincialis*) were obtained from a commercial shellfish farm (Palavas, France, Gulf of Lion) during winter. The hemolymph of 20 mussels (approximately 0.5 mL/animal) was extracted via a 23G needle plus syringe, directly into an equal volume of the anti-aggregant buffer, Modified Alsever Solution (MAS, Bachère et al. 1988), and immediately centrifuged at 800 g for 15 min at 4 °C. The cell pellet was air-dried and stored at −80 °C until required.

Actin-Specific and Ribosomal 18S-Specific DNA Probes and Screening of cDNA Library

Poly(A)$^+$ RNA from adult mussel hemocytes were used to construct a cDNA library in the ZAP Express Vector (Stratagene, La Jolla). Reverse transcription and polymerase chain reaction (PCR) were used to prepare a DNA probe corresponding to hemocytic actin. Three μg of total RNA (see below for RNA isolation) were submitted to reverse transcription using the Ready-to-Go You-prime first strand beads kit (Pharmacia). One-fifth of the reaction was directly used as a template for PCR with two primers designed from a consensus actin sequence by M. E. Unger and G. Roesijadi (1993) for the oyster *Crassostrea virginica*, and renamed Avi1 (5′TAA TCC ACA TCT GCT GGA AGG TGG 3′) and Avi2 (5′TCA CCA ACT GGG ATG ACA TGG 3′). PCR was performed in 50 μL with 40 cycles consisting of 1 min at 94 °C, 1 min at 60 °C and 1 min at 72 °C with 1.5 mM $MgCl_2$ and 1 μM primers.

The resulting 846 base pair fragment corresponding to an actin cDNA fragment was cloned using the pCR-Script Amp SK (+) Cloning Kit (Stratagene, La Jolla). The plasmid containing the actin cDNA fragment was called pBSAct.846. The pBSAct.846 insert was labeled with [^{32}P] by random priming using the Ready-

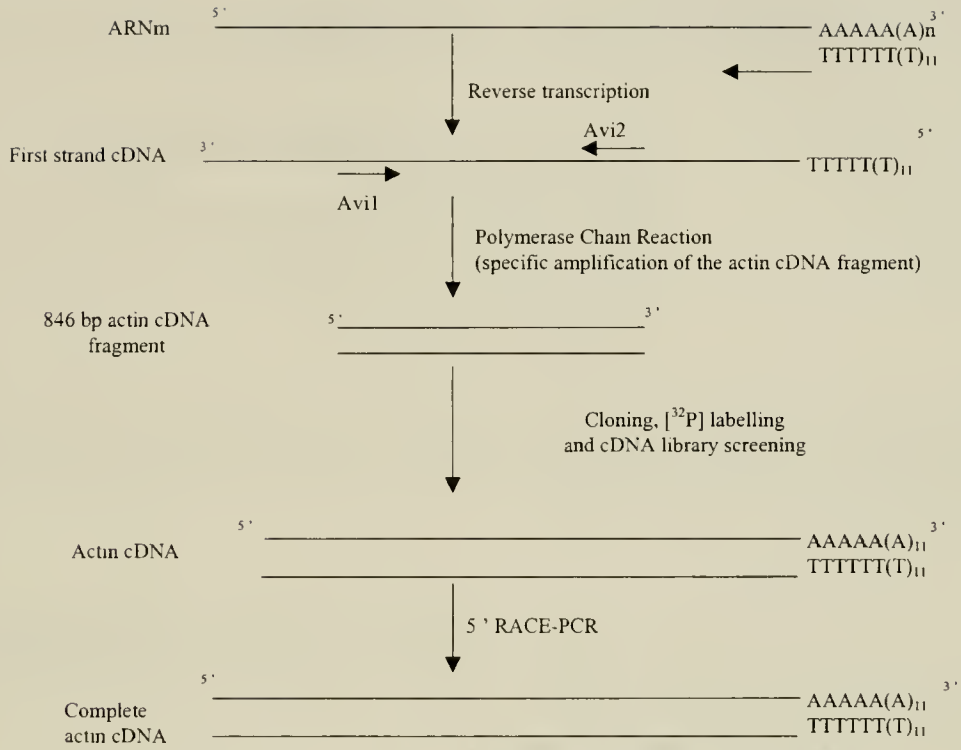

Figure 1. Complete characterization of *Mytilus galloprovincialis actin* cDNA (Mya2).

to-go DNA labeling kit (Pharmacia Biotech.) and used to screen 400,000 plaques from the cDNA library that has been transferred to Hybond-N filter membranes (Amersham Corp.). High stringency hybridization was carried out overnight at 65 °C in 5X Denhardt's solution, 5X SSPE (Sambrook et al. 1989), 0.1% SDS, 100 μg/mL salmon sperm DNA. The filters were washed in a solution of 0.5X SSC containing 0.1% SDS at 65 °C, followed by autoradiography. A secondary screening was performed to purify the positive clones. Phagemids were obtained by *in vivo* excision according to the manufacturer's instructions and sequenced on both strands.

To compare the relative expression of actin messenger in various tissues of the mussel (see Northern-blot analysis), a probe detecting a 18s rRNA, present at the same level in all tissues was designed. As such, a sense oligonucleotide primer (5'TGACCTCGCGGAAAGAGCGC 3') and an antisense oligonucleotide primer (5'AGGGGACGTAATCAACGCGAGC 3') were designed from the sequence of the ribosomal RNA small subunit (Kenchington et al. 1995) and used in PCR experiments. Five hundred ng of mussel genomic DNA were submitted to amplification in 50 μL using 35 cycles consisting of 1 min at 94 °C, 1 min at 60 °C and 1 min at 72 °C with 1.5 mM $MgCl_2$ and 1 μM primers (Fig. 1).

Northern Blot Analysis

The hemocytes from 4 mussels collected together during winter (8×10^6 cells per animal) were centrifuged and resuspended in 1 mL of Trizol (Life Technologies). Immediately after hemolymph collection, the mantle, foot, labial palps, gills, hepatopancreas, and adductor muscle were excised from the same animals and washed extensively in sterile-filtered seawater. The tissues (100 mg of each) were homogenized in 1 mL of Trizol with 30 strokes of a Potter homogenizer to break the cells in 1 mL of Trizol and total RNA was extracted according to the manufacturer's protocol (Life Technologies). Five μg of total RNA was isolated from each tissue, pooled from each animal (20 μg total per tissue) and subsequently analyzed.

Total RNA and size markers were electrophoretically separated on a 1.2% agarose gel containing 17% formaldehyde, transferred and cross-linked to a Hybond-N filter membrane (Amersham) which was then stained with methylene blue. The membrane was hybridized with the [^{32}P]-labeled actin cDNA probe in a solution containing formamide (50%), 5X SSC, 8X Denhardt's solution, sodium phosphate (0.05 M pH 6.5), SDS (0.1%) and salmon sperm (100 μg/mL) at 55 °C for 12 h. The membrane was washed in 0.2 X SSC, 0.1% SDS at 65 °C and autoradiography was carried out. After autoradiography, the membrane was stripped by incubating the blot with a boiling solution of 0.1% SDS for 1 hour and submitted to a subsequent hybridization with the [^{32}P]-labeled DNA probe revealing 18S rRNA.

Rapid Amplification of 5' cDNA end (RACE-PCR) and PCR

To obtain the complete cDNA sequence corresponding to the actin mRNA, a 5' RACE-PCR was undertaken. This was performed using the 5' RACE Kit (Boehringer Mannheim) following the manufacturer's instruction. Briefly, 2 μg of total RNA from the pooled hemocytes were submitted to reverse transcription using antisense 24 nucleotides primer (5'ATGATGTCTGTTTTATAAAGTTAT 3'), deduced from the actin cDNA sequence. After first-strand cDNA synthesis and addition of a poly(A) tail at its 5' end, PCR was performed with an oligo d(T)-anchor primer and a nested antisense primer of 24 nucleotides (5'AGAGGAGTATCTCACCCTGACTTC 3') deduced from the actin cDNA sequence. Amplification was performed according to the following program: melting at 94 °C for 1 min, annealing at 50 °C for 1 min, elongation at 72 °C for 1 min (35 cycles). The PCR products were cloned using the pCR-Script Amp SK (+) Cloning Kit (Stratagene) and several different cDNA clones were sequenced.

Figure 2. Nucleotide sequence and deduced amino acid sequence of the *Mytilus galloprovincialis actin* cDNA (Mya2). Untranslated regions in lower-case letters. Start codon in boldface letters. Polyadenylation signal is underlined.

RESULTS AND DISCUSSION

After colony blot of the cDNA library, 5 positive clones among 352 were chosen and submitted to secondary screening for isolation. The corresponding phagemids were obtained by *in vivo* excision and the longest was sequenced on both strands (Fig. 2). This complete actin cDNA (named *Mya2*, Genbank accession number AF157491) shows a potential coding sequence stretching over 1618 bp and codes for a typical 376 amino acids actin. The 5′ RACE-PCR experiment allowed an additional 19 base pairs to be added and helped to suggest the Transcription Start Point (+1). Best homologies in amino acid sequence were found with the bivalve *Placopecten magellanicus;* 97.8%, the nematode *Caenorhabditis elegans;* 96.2%, the brine shrimp *Artemia sp;* 96.5% and the silk worm *Bombyx mori;* 96.2%. For nucleic acid sequence, best homologies are found with the scallop *Placopecten*

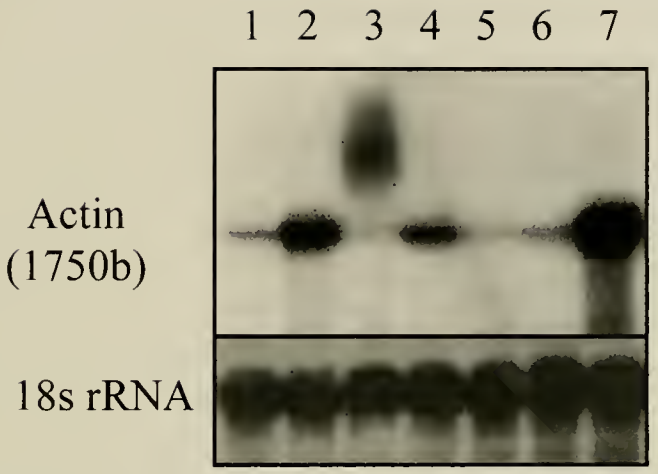

Figure 3. Northern blot analysis of RNAs from various tissues of the mussel. Twenty µg of total RNAs from various tissues: 1, hemocytes; 2, mantle; 3, foot; 4, labial palps; 5, gills; 6, hepatopancreas; 7, adductor muscle. All were separated by 1% agarose-formaldehyde gel electrophoresis, blotted and hybridized with ^{32}P-labeled cDNA probe corresponding to actin cDNA. The RNA relative amounts of the various tissues are evaluated by hybridizing the same membrane with a probe corresponding to the 18S rRNAs because the actin mRNA probed is differentially expressed in the different tissues tested.

magellanicus (85%), the zebra mussel *Dreissena polymorpha* (84%) and the oyster *Crassostrea gigas* (83%). According to Vandekerckhove and Weber, (1978) who described 20 residues discriminating muscular and cytoplasmic actins, *Mya2* displays feature of cytoplasmic actin for 10 codons, while 3 of them show the mark of muscular actins. The cystein in position #2 is a common feature among invertebrate actins, although some exceptions are documented. Actin mRNAs were detected in various tissues as demonstrated by Northern Blot experiments using the *Mya2* cDNA as probe (Fig. 3). The signal is particularly strong in the mantle, the labial palps, and the adductor muscle. This strong signals, however, are mainly due to the recognition by the probe of all forms of actin mRNA. Indeed, conservation is so high (particularly within the used probe) that both muscular and cytoplasmic forms are highlighted giving a cumulative signal.

Several isoforms have been reported in higher vertebrates, divided into muscular and non-muscular actins (Rubenstein 1990). Due to the high level of similarity with the other actin genes, this sequence may not be suitable for intra- and inter-species phylogenetic studies. Nevertheless, the potential availability of intronic non-expressed sequences within this actin gene would be of interest in developing a selectively neutral marker as has already been done in other bivalves (Corte-Real et al. 1994; Ohresser et al. 1997). Furthermore, this complete cDNA sequence can now be used in regulation studies as an expression level standard as well as an anchor in the search for the complete gene including the proximal promoter involved in its expression pattern.

GROWTH OF SEED MUSSEL (*MYTILUS GALLOPROVINCIALIS* LMK): EFFECTS OF ENVIRONMENTAL PARAMETERS AND SEED ORIGIN

J. M. F. BABARRO, M. J. FERNÁNDEZ-REIRIZ,* AND U. LABARTA

CSIC Instituto de Investigaciones Marinas, c/Eduardo Cabello, 6, E-36208 Vigo, Spain

ABSTRACT Mussel seeds (*Mytilus galloprovincialis* Lmk) of similar weight and length from two different origins (rocky shore and collector ropes) were cultivated on a raft in the Ría de Arousa (northwest Spain), from seeding to thinning out, for a total period of 208 days (November 1995 through July 1996). Weight increase rates for the seed from collector ropes were higher than those for the seed from rocky shore, and the growth rate variations during the cultivation period were associated with the environmental parameters measured (chlorophyll *a* and temperature). The origin of the seed was also found to be a significant factor. The condition index (CI) of the seed from collector ropes was significantly greater than that of the rocky shore seed at the beginning of the cultivation time. Both mussel seeds showed a similar CI after 70 days and during the rest of the cultivation time. Although allometric coefficient values for the relation total dry weight-length showed a similar range for both types of seed, no significant differences were observed for this coefficient in collector rope mussels throughout the cultivation period. Rocky shore mussels showed, on the contrary, a significant increase for this allometric coefficient value throughout the cultivation period. These preliminary results from the total dry weight-length relationship obtained here and the change of CI differences serve to strengthen the hypothesis of a physiological basis for the differences in growth between both types of seed mussel. This finding could be related to the different features of the original habitats of the two types of seed, in terms of the cycles of availability of food and exposure to the air.

KEY WORDS: Mussel, growth, environmental parameters, condition index, allometric functions

INTRODUCTION

Mussel (*Mytilus galloprovincialis* Lmk) cultivation in Galicia and other cultivation zones (Pérez Camacho et al. 1995) is dependent on the availability of large quantities of seed, which can be obtained from two very different origins: coastal stocks from the rocky shoreline, and collector ropes suspended from cultivation rafts.

Previous studies about the growth of these two types of seed in the Ría de Arousa disagree as to their growth potential from seeding to thinning out. On the one hand, Pérez Camacho et al. (1995) found differences in growth rates and condition indices of the mussels that they attributed to the origin of the seed, with collector rope seed having the highest values. On the other hand, Fuentes et al. (1998) concluded that neither of the two types of mussel seed (rocky shore and collector rope) has a higher growth potential, although the authors do recommend that mussel farmers "use seed from collector ropes due to their significantly larger size at harvest time."

Dickie et al. (1984), Page and Hubbard (1987), and Fuentes et al. (1992) have all established that the origin of the seed has a significant effect on mortality rates, although not on growth. However, Peterson and Beal (1989) and Rawson and Hilbish (1991) have observed a significant effect of origin on growth, which they explain as being due to genetic differences.

Bayne and Newell (1983) point to the effect of endogenous factors (physiological condition, size, and genotype) and the specific environmental conditions of the area in question as being two of the factors that most affect growth in bivalve molluscs. In the case of environmental factors, it has been shown that in areas where temperature, for example, is not a limiting factor, the availability of food affects growth to a very large extent (Mallet et al. 1987, Stirling and Okumus 1994, Sukhotin and Maximovich 1994, Widdows et al. 1997).

The aim of this study was to investigate the effects of seed origin and environmental parameters on different growth indicators (growth rate, condition index [CI], and the allometric relation weight-length).

MATERIALS AND METHODS

Experimental Design

Seed of *Mytilus galloprovincialis* Lmk, approximately 20 mm long, was gathered from the rocky coastline and from raft collector ropes in the mid-to-outer area of the Ría de Arousa (Galicia, northwest Spain) in November 1995. Both types of seed, from the same year class, came from the spawning period in the previous spring-summer, and the sampling locations were 2 km away from each other. Experimental cultivation, which was carried out in a raft usually used for the culture in the Ria de Arousa (500 m^2), commenced in winter in order to minimize any possible advantages that collector rope seed may have as a result of its being better adapted to cultivation on the raft. The experiment ran until June 1996 (208 days), thus covering the first stage in mussel cultivation, from seeding to thinning out (50–60 mm). Sixteen cultivation ropes (12 m) were used, eight for each type of seed, alternately placed and having a density of 19 kg of seed per rope (1.6 kg/m of rope or 2,600 individuals per meter of rope). Sampling was performed by removing mussels from adjacent ropes at an average depth of 2–4 m for both types of seed.

Initial average lengths (± standard deviation) were 22.5 ± 1.5 mm for the seed from collector ropes and 19.0 ± 1.9 mm for that from the rocky shore. Average total dry weights were 0.36 ± 0.06 and 0.27 ± 0.06 g/individual, respectively. No significant differences were observed for length and dry weight between both types of seed at the outset of the experiment (analysis of variance [ANOVA]; $P > 0.05$).

Environmental Parameters

Natural seston was described as total particulate matter (TPM, mg/L), particulate organic matter (POM, mg/L), particulate inor-

*Corresponding author. E-mail: mjreiriz@iim.csic.es

ganic matter (PIM, mg/L), total particulate volume (Vol, mm^3/L), and chlorophyll *a* (chl-*a*, µg/L). The quality of the seston was expressed as Q_1 (POM/TPM) and by the chl-*a*/TPM index.

The values of chl-*a*, as well as temperature (°C) and salinity (‰) of the water column, were supplied by the Marine Environment Quality Control Centre of the Consellería de Pesca, Marisqueo e Acuicultura (Ministry of Fisheries, Shellfisheries and Aquaculture) of the Xunta de Galicia (Galician Regional Government). chl-*a* was calculated from the fluorescence data.

Seawater samples were filtered onto pre-ashed (450°C for 4 h) and weighed GFC filters and rinsed with isotonic ammonium formate (0.5 M). Total dry matter was established and the weight increment determined after drying the filters to constant weight at 110 °C for 12 h with an accuracy of 0.001 mg. Organic matter corresponded to the weight loss after ignition at 450 °C for 4 h in a muffle furnace. Particulate volume per liter of seawater was determined by counting in the range of 2–56 µm using a Coulter Counter Multisizer II fitted with a 100 µm-aperture tube.

Mussel Sampling

Duplicate samples of 200–350 individuals were taken from adjacent ropes, which corresponded to both types of seed mussel after 70, 148, and 208 days.

Individual mussel length (L) was measured to the nearest 1 mm using calipers, and each sample was divided into 1-mm length classes. Adjusted length was given by the formula: $L = (C_L\ F)/N$ (Box et al. 1989), where C_L is the individual length class, F is the frequency, and N is the total number of individuals. Subsamples of 5–15 mussels were each taken from five to six length classes covering the entire size range and used to determine total dry weight (DW_{total}) and organic weight of tissues (OW_{tissue}). After cutting adductor muscles and allowing intervalvar water to drain by placing the mussels with their ventral edge on filter paper, tissues were dissected and both shell valves (DW_{shell}) and soft tissues (DW_{tissue}) were weighed after drying at 100°C until constant weight was obtained. We ashed the soft tissues at 450°C for 48 h to determine OW_{tissue}, with an accuracy of 0.01 g in all cases.

CI was calculated from the ratio of tissue dry weight (DW_{tissue}) and the dry weight of the valves (DW_{shell}) according to the equation $CI = (DW_{tissue} / DW_{shell})\ 100$ (Freeman 1974).

Data Analysis

Regression models were calculated for the logarithm of total dry weight (log DW_{total}), tissue dry weight (log DW_{tissue}), and tissue organic weight (log OW_{tissue}) versus logarithm of length (log L) relationships from data obtained for five or six length classes covering the entire length class range from 10–15 mm above and below the mean length: $\log W = \log a + b \log L$. Analysis of covariance (ANCOVA; Snedecor and Cochran 1980) was used to make a comparison of these functions between both types of seed mussel and the change of allometric coefficient (b) in the experiment.

The confidence interval for the difference in length and weight between the months of the cultivation period studied that gives the growth rate for each stage was given by the formula: $X_{t+1} - X_t \pm [t_{(1-\alpha/2,k)}\ Sp \sqrt{(1/n_{t+1} + 1/n_t)}]$ (Canavos 1988), where X_{t+1} and X_t are the mean values for length and weight at each end of the intervals, Sp^2 is the variance at each end of the interval, n_{t+1} and n_t are the number of samples at each end of the interval, and $t_{(1-\alpha/2,k)}$ is the Student *t*-distribution value with 95% confidence and k degrees of freedom ($k = n_{t+1} + n_t - 2$).

Comparison of mean values of growth rate was carried out with an ANOVA. Homogeneity of variances was tested by the Bartlett test (Snedecor and Cochran 1980), and correction for heterogeneity (when required) was performed by reciprocal or logarithmic transformation data. In cases in which homogeneity was not obtained after these transformations had been carried out, the Kruskall-Wallis nonparametric test was used.

The effects of environmental parameters and origin of seed mussel on the growth rate were tested by stepwise multiple regression. Seed origin was introduced with values 0 and 1 for collector rope and rocky shore mussels, respectively. Length and dry weight values of growth rate were transformed by $\log_{10}(x + 1)$ to stabilize variances.

RESULTS

Environmental Parameters

Variation in temperature (°C) took place within a narrow range, there being a difference of only 2.7 °C between the maximum and minimum temperatures during the whole of the experimental period (Fig. 1A). Temperature was high at the beginning of the cultivation period (15.5 °C) and then decreased in zigzag until the minimum temperature was reached in February (12.9 °C). From then on, throughout the spring months, there was a steady increase in temperature.

Salinity (‰) was dependent on rainfall. Average values for the area (31.3–35.2‰) were obtained at the outset, and they gradually decreased until January, when the minimum value (28.0‰) was recorded. Salinity then increased during the spring months and finally reached its maximum value at the end of the cultivation period in July (35.6‰; Fig. 1A).

High values for TPM were registered in February through April (0.9–1.4 mg/L; Fig. 1B), in contrast with the low values obtained throughout the winter months. However, the maximum of TPM occurred at the beginning of January (2.6 mg/L; Fig. 1B), which can be related to maximums in POM (1 mg/L) and especially in PIM (1.6 mg/L). With the single exception of this maximum value,

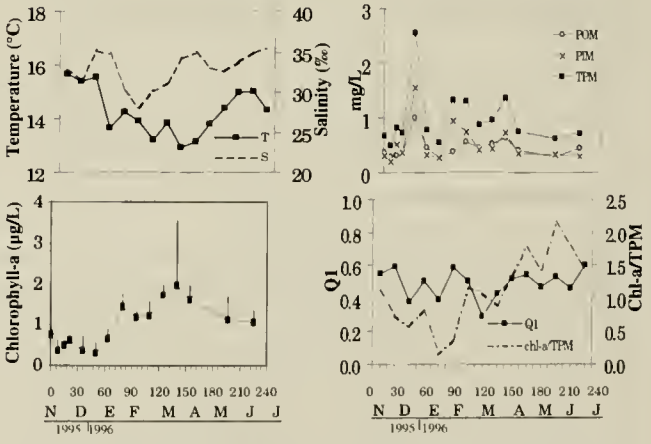

Figure 1. Variation of average values (mean SD) of temperature (°C) and salinity (‰) (A); TPM (mg/L), POM (mg/L), and PIM (mg/L) (B); chl-*a* (g/L) (C); and quality of the seston (Q_1 µg POM/TPM) and chl-*a*/TPM index (D), during the experimental period November 1995 through July 1996.

POM was higher during the spring (>0.5 mg/L) than during the winter (0.3 mg/L). Fluctuations in chl-*a* produced two peaks in February and April (1.4 and 2.0 μg/L, respectively; Fig. 1C) after the low values recorded during the initial stages of the experiment (0.3–0.8 μg/L).

Q_1 varied between 0.3 and 0.6, showing a greater oscillation in winter and a narrower range of fluctuation around 0.5 during spring, which corresponds to the value that is generally obtained for the Ría de Arousa (Fig. 1D). The chl-*a*/TPM index varies to a much greater extent, with low values being recorded in winter (0.1–1.1; Fig. 1D) and then increasing from February on to reach a peak in April and June (2.1).

Growth

The growth rate in terms of length (mm/mo) shows minimum values in winter (1.5 and 2.0 mm/mo for collector rope and rocky shore mussels, respectively; $P > 0.05$) and maximum levels from April through June (9.1 and 6.8 mm/mo for the same two mussel populations, respectively; $P > 0.05$; Table 1). The average growth rates for the whole period November through June were thus similar for both types of mussel seed, at 4.8 and 4.5 mm/mo, respectively ($P > 0.05$).

Weight growth shows a trend similar to that for length over the cultivation period, with the minimum in winter (0.07 g DW_{total}/mo for both seed types) and the maximum in the April through June period, when the collector rope mussels showed significantly higher values (1.60 g DW_{total}/mo) than the rocky shore mussels (0.86 g DW_{total}/mo) ($P < 0.05$; Table 1). The overall November through June values for DW_{total} growth rates are 50% higher for the former (0.61 g DW_{total}/mo) than for the latter (0.41 g DW_{total}/mo) ($P < 0.05$; Table 1). The differences between these two groups of mussels in the final stages of cultivation (April through June) and in the overall average values (November through June) also apply to organic and dry weight of tissues (OW_{tissue} and DW_{tissue}, respectively), with collector rope mussels once again showing higher values (see Table 1).

The variation of growth rate in terms of both length and total dry weight in this study bore a significant relationship to fluctuations in the environmental parameters chl-*a* and temperature of the water column, in this order of importance (Table 2). Both of these environmental variables show positive and significant coefficients ($P < 0.001$ for chl-*a* and $P < 0.05$ for temperature vs. growth rate for length), with chl-*a* being the major component of the variance (40.1 and 56.6% for growth rates for dry weight and length, respectively). A significant but residual effect ($P = 0.040$) was also noted for seed origin vs. growth rate for total dry weight (Table 2).

Condition Index

CI for collector rope mussels was 33% higher than that for rocky shore mussels ($P < 0.001$) at the beginning of the cultivation period (Table 3). After 70 days, similar values of CI were obtained for both groups of mussels ($P > 0.05$), and this remained the case until the end of the cultivation period without differences between them. The significant increase in CI ($P < 0.001$) for both groups of mussels between 70 and 148 cultivation days, which corresponds with the period February through April, is remarkable.

Allometric Functions

Values a and b of the allometric function weight-length ($W = a L^b$) for each mussel seed during the cultivation period are shown in Table 4. No significant differences among the slopes (b) of both groups of mussels at any time during the cultivation period were detected when an ANCOVA was performed on the linear transformations of these functions ($P > 0.05$). However, the intercepts for collector rope mussels were significantly higher at the end of the cultivation period (June) in all cases ($P < 0.001$ for DW_{total} and OW_{tissue} vs. L and $P < 0.01$ for DW_{tissue} vs. L; Table 4). Significant differences were also obtained for the intercepts in February ($P < 0.05$) and November ($P < 0.01$) for the relations DW_{tissue} and OW_{tissue} versus L, respectively, in which higher values were once more recorded for the collector rope mussels (Table 4).

Concerning shell weight, we found no differences at the onset of the experiment (0.32 ± 0.05 and 0.25 ± 0.06 g for collector rope and rocky shore mussels, respectively; $P > 0.05$). The same tendency was maintained during the cultivation period except at the end (June), when mussels from collector ropes presented heavier shells (3.63 ± 0.17 g) than rocky shore ones (2.41 ± 0.23 g) ($P < 0.001$).

A second ANCOVA was performed on the fluctuation of the values a and b in the relation DW_{total}-L over the cultivation period, for each seed type independently. The results are shown in Table 5. The power b gives similar values throughout the cultivation period for collector rope mussels ($P > 0.05$), yet when intercept a is recalculated for a common power (Rec.a), it gradually increases over time, with significant differences between November and April ($P < 0.05$) and maximums occurring in June ($P < 0.001$). On

A. $N = 18$; $r^2 = 0.708$; $F_{2,15} = 18.155$; $P < 0.001$
B. $N = 18$; $r^2 = 0.878$; $F_{3,14} = 33.620$; $P < 0.001$

Mean intercept and coefficients ± SD. Origin is defined with values 0 and 1 for collector ropes and rocky shore mussels respectively. Percentage values mean proportion of accumulated variance with inclusion of different factors (NS not significant).
* $P < 0.05$, significant difference from 0.
† $P < 0.001$, significant difference from 0.

the other hand, rocky shore mussels showed a steady and significant increase of slope (b) over time ($P < 0.05$; Table 5), reaching maximum values in June (2.507), although significant differences were already evident between the allometric coefficients for November (2.276) and April (2.491) ($P < 0.01$).

DISCUSSION

The variations in factors such as temperature, salinity, and chl-*a* in the area studied are consistent with previous descriptions of the Galician Rías (Fraga 1996). Abundant rainfall and low levels of sunlight until February are the reason for low salinity and the concentration of chl-*a* in the winter months. The maximum values of TPM and POM that occurred in January constitute an exception to the winter-spring pattern that characterizes the natural seston variability and reveal the effect that frequent storms have on a shallow area such as this at this time of year, leading to a resuspension of previously sedimented particles. The mainly sedimentary origin of this sudden increase in POM in January is supported by the low winter values of the chl-*a*/TPM index. The peak levels of phytoplankton that occur in the Galician Rías can be related either to an increase in sunlight (the first chl-*a* peak occurs in mid-February) or to the upwelling of nitrates/silicates of the water caused by the appearance of North Atlantic Central Water (NACW). NACW is the main reason for the spring upwelling in the Galician Rías, which is represented by a second and higher chl-*a* peak in mid-April.

Among the environmental parameters studied, the availability of plankton in the water column in the form of chl-*a* and water temperature had a significant effect on the variations in growth rate. Both of these factors have previously been signalled as being responsible for most of the variation in the growth rate of bivalve molluscs (Bayne and Newell 1983), and the fact that in the present study chl-*a* has the greater effect of the two supports earlier results (Pérez Camacho et al. 1995). In temperate waters, such as Ría de Arousa, temperature fluctuations are not as marked as they are in extreme environments where fluctuations in this factor play a more important role (Kautsky 1982, Sukhotin and Kulakowski 1992). Therefore, variations in growth rate in temperate waters have been associated with the availability of food (Page and Hubbard 1987, Thompson and Nichols 1988, Fernández-Reiriz et al. 1996).

Growth rate variation, estimated here with low values during winter and maximums in spring, follow a pattern similar to that found in other studies (Freeman and Dickie 1979, Pieters et al. 1980, Kautsky 1982, Loo and Rosenberg 1983, Skidmore and Chew 1985, Page and Hubbard 1987, Mallet et al. 1987). The maximum growth rates for length, which were recorded in spring (9.1 and 6.8 mm/mo for collector rope and rocky shore mussels, respectively), agree with the findings described by Pérez Camacho et al. (1995) for the same time of year and both types of seed in the Ría de Arousa. The increase in length after the experimental period (31–33 mm for 208 days; 4.4–4.7 mm/mo, with both types of seed included) is comparable to that of a previous paper on the Ria de Arousa for a similar period of the year, 5.6–5.8 mm/mo (Fuentes et al. 1998). Pérez Camacho et al. (1995) found higher growth rates of 7–9 mm/mo. However, it is necessary take into account that this experiment began in April and ended 90 days later, which means favorable conditions from the beginning with regard to temperature and seston availability and quality. The lower growth rates obtained by Fuentes et al. (1992) also with *M. galloprovincialis* in the Ria de Arousa (2.4 mm after 3 mo) can be attributed to the cultivation technique used (plastic cages).

These differences also appear in the cultivation period needed before thinning out, which is greater in experiments that commence in winter (5 and 7 mo, respectively, for Fuentes et al. 1998 and the present study) than in those that start in spring (3 mo; Pérez Camacho et al. 1995).

Although Fuentes et al. (1998) recommend that seed from collector ropes should be used for cultivation, since it reaches greater length and/or weight than rocky shore seed, they differ from Pérez Camacho et al. (1995) as to the existence of a difference in growth rates from seeding to thinning out. Their reasoning is based on the fact that if more than one cohort were included in the process of gathering the rocky shore seed, this may well explain the different growth rates reported by the latter authors. The results of this study

TABLE 3.

Condition index (CI) values for both types of seed mussel during their cultivation on a raft.

Month	Days of Cultivation	CI	
		Collector Ropes	Rocky Shore
November	0	15.84 ± 2.44*	11.87 ± 0.97
February	70	13.27 ± 0.87 NS	12.08 ± 1.86

a and b values are parameters in the equation $W = aL^b$; ANCOVA ANOVA was made after logarithm transformation: log W = log a + b log L. When there were no differences in slopes (b) of the relationship, a common exponent was therefore calculated and used to recalculate values for the parameter a (Rec. a). NS, not significant.

do nevertheless point out a difference in growth rates, especially for weight, that are also related to variability of environmental parameters during the cultivation period. This study is also in concordance with Pérez Camacho et al. (1995), who showed that initial size (weight/length) has no effect on the results, either because the experiment was designed with this condition in mind (as in this study) or because the statistical analysis (multivariate ANOVA) performed on the results showed this to be the case (Pérez Camacho et al. 1995). With reference to the study by Fuentes et al. (1998), the differences observed in the initial size of both types of seed (0.6 cm for rocky shore mussels and 2.1 cm for collector rope mussels), as well as the high density of mussels on the ropes (5,000 individuals per meter), which contrasts with the 2,600 individuals per meter of the present study and the 2,000 individuals per meter of Pérez Camacho et al. (1995), may have affected their results, given the effect that both of the above-mentioned factors (initial size and density) may have on growth (Sukhotin and Maximovich 1994, Eldridge et al. 1979, Fernández-Reiriz et al. 1996).

TABLE 5.

Results of ANCOVA on data relating DW_{total} (mg) to shell length (mm).

Month	Collector Ropes h	a	Rec. a	n	Rocky Shore h	a	Rec. a	n
November	2.247	0.328	0.209	10	2.276	0.326	—	10
February	2.505	0.152	0.237	15	2.430	0.194	—	15
April	2.397	0.232	0.249	11	2.491	0.179	—	11
June	2.212	0.644	0.319	10	2.507	0.167	—	10

Collector ropes:

Comparison among slopes, F = 1.091 (DF = 3,38) $P > 0.05$.

$b_{common} = 2.384$.

Comparison among intercepts, F = 12.944 (DF = 3,41) $P < 0.001$.

Rocky shore:

Comparison among slopes, F = 3.134 (DF = 3,38) $P < 0.05$

a and b are parameters in the equation $DW_{total} = aL^b$ (see Table 4, top). Rec. a represents recalculated intercept for common slope.

Although our results show a difference in growth rates between collector rope and rocky shore mussels, as was previously observed by Pérez Camacho et al. (1995), it should be pointed out that these differences become more apparent in those months that most favor growth (April through June), which is precisely the period in which the experiment by Pérez Camacho et al. (1995) took place, and just as was the case in their experiment, the most marked differences in our results are those for growth in wet weight and tissue weight. A higher growth efficiency for collector mussels when environmental conditions (temperature and overall quality of food) are more favorable, resulting in a more positive scope for growth, and the persistence of different metabolic patterns due to immersion-emersion periods that are indicative of anaerobic pathways for rocky shore mussels, could help us to understand such different growth responses. Genetic factors could also explain a significant proportion of the variances in production/growth of mussels (Widdows et al. 1984, Mallet et al. 1987), since it has been described that mussels exhibit high levels of genetic variability measured as enzyme polymorphisms both on a micro- and a macrogeographic scale (see Hawkins and Bayne 1992). Additionally, energy-saving mechanisms related to respiration metabolism have been described for those animals, which live in the intertidal locations. Metabolic depression and anaerobiosis are clearly implicated as key factors of energy conservation to withstand emersion conditions in order to compensate for reduced

feeding time with respect to sublittoral animals (de Zwaan and Mathieu 1992).

Both terms (physiological rates and metabolic patterns) are being tested for both types of seed mussel cultivated on suspended conditions in Arousa.

The use of the allometric function weight-length in growth studies is firmly established (Hickman 1979, Rodhouse et al. 1984, Sprung 1995, Sará et al. 1998, among others). A correspondence has occasionally been established between the variation in the allometric coefficient and local food conditions (Sará et al. 1998). In this study, we did not measure the original weight-length relationship of intertidal mussels before putting them on the raft. However, the fact that the experiment began a few hours after the seed mussels were gathered from their environments suggests that this relationship is similar to that which these mussels might show in their original habitat. An ANCOVA that was performed for this weight-length relationship in rocky shore mussels with regard to cultivation time period showed changes in the b parameter value (more evident between slopes of November and April), whereas collector rope mussels presented no differences in this value throughout the cultivation period. This probably means that environmental changes for rocky shore mussels, when they are put under immersed conditions on the raft, might be responsible for such a response of the allometric functions.

The initial differences in the CI of the two types of mussel seed can be attributed to their original habitats, which differ greatly with regard to the availability of food and their respective situations of emersion-immersion. The disappearance of these differences after 70 days may be related to the changes in physiological responses resulting from a new environmental situation (Bayne et al. 1984, 1987), although these differences may well persist for some time (Widdows et al. 1984, Iglesias et al. 1996).

Given the experimental design in this study, any effects on our results of a genetic nature that have occasionally been used to explain differences in growth (Peterson and Beal 1989, Rawson and Hilbish 1991) would be possible when genetic factors play a part in the choice of substrate (rocky shore or collector rope) by larvae in the Ría de Arousa or when different cohorts are involved. As has previously been mentioned by Pérez Camacho et al. (1995), an alternative hypothesis would be to consider a physiological adaptation response of each seed to its habitat of origin, which would imply that cultivation starts from different physiological states, which is described by Mallet et al. (1987) as ecological memory. This ecological memory would condition the physiological response of the seed to its new environmental situation, as shown by an increase in the CI for the rocky shore seed.

We can consider that the aim of slowing down the initial growth rates in order to minimize any possible advantages for the collector rope mussels has been achieved. This would explain why the differences observed in growth rates between the two types of seed are less marked than those recorded by Pérez Camacho et al. (1995) during the first stage of the cultivation period. Although the allometric coefficients for both types of seed need to be tested with regard to their original habitat for establishing more properly habitat-dependent changes, the CI differences maintained in both seed types supports the hypothesis that there is an underlying physiological basis for the difference in their respective growth rates. Moreover, given the experimental conditions under which the present study was performed and taking into account the CI changes, the physiological parameters of the two types of seed could be expected to converge.

FEEDING BEHAVIOR OF SEED MUSSEL *MYTILUS GALLOPROVINCIALIS*: ENVIRONMENTAL PARAMETERS AND SEED ORIGIN

J. M. F. BABARRO, M. J. FERNÁNDEZ-REIRIZ,* AND U. LABARTA
CSIC Instituto de Investigaciones Marinas
c/Eduardo Cabello, 6, E-36208 Vigo, Spain

ABSTRACT Mussel seed (*Mytilus galloprovincialis*) from two original habitats (rocky shore and collector ropes) was cultivated on a raft in the Ría de Arousa (northwest Spain), for a period of 226 days (November 1995 through June 1996), from seeding to thinning out, during which time the behavior of clearance rates (CR) and ingestion rates (IR) was studied. The study of these two physiological parameters of energy acquisition (CR and IR) demonstrates that the two types of seed showed significant differences in these parameters at the start of the experiment and after the first 8 days on the raft. After 15 days, large increases in these physiological rates were observed for both types of seed, with the increase for the rocky shore mussels doubling that of the collector rope specimens. These increases led to the disappearance of the significant differences in CR and IR between both seed origins, with this situation being maintained for the remainder of the experimental period. The variation in CR follows a seasonal pattern, with low values being recorded in winter and increasing in spring and summer. Minor seasonal variations of total seston concentration are counterbalanced by an inverse variation in organic content, and so organic IR followed a pattern similar to that of CR. This seasonal variation can be attributed to fluctuations in the factors food quality (Q_1) and temperature, in this order, as the use of multiple regression analysis has proved. Seed origin had a significant effect as a factor of interaction with food quality Q_1, probably because of differences between the original habitats of the seed (rocky shore and collector ropes) in the latter factor. Although in this study food quality has been expressed in terms of organic content (Q_1 = organic/total particulate matter), the content of phytoplankton as chlorophyll *a* may have had an important effect on the variation of both of these physiological rates. A significant exponential relationship has been established between the IR and the content in total particulate matter, which suggests regulation processes according to the amount of natural food available based on a decrease of CR.

KEY WORDS: *Mytilus galloprovincialis*, mussel seed, clearance rate, and ingestion rate, Ría de Arousa

INTRODUCTION

Clearance rates (CRs) and ingestion rates (IRs) determine the amount of food that enters the digestive system of bivalve molluscs. The variability observed in these physiological parameters has been interpreted in terms of the ability of these animals to adapt to the specific environmental and nutritional conditions of their habitat (Widdows et al. 1984; Navarro et al. 1991; Okumus and Stirling 1994; Iglesias et al. 1996). The relationship between IR and food concentration depends on CR, which in turn is affected by environmental factors. Hawkins and Bayne (1992) proposed the use of multifactorial analyses to ascertain the relevance and ecological complexity of the set of environmental variables, as well as their interaction with physiological parameters.

When attempting to determine the extent of the influence of habitat, transplant experiments are considered to be the ideal way of analyzing the effect of the variability attached to the environment in which the individuals lived previously, in connection with what Mallet et al. (1987) termed ecological memory. Previous comparative studies of mussel seed gathered from a rocky shore and from collector ropes and then cultivated on a raft established the existence of a significant effect of the seed origin on growth rate (Pérez Camacho et al. 1995; Babarro et al. 2000), with this effect being associated with physiological parameters.

The extent of time needed for CR and IR to acclimate to new environmental conditions has been reported in various studies (4.5 mo [Okumus and Stirling 1994] and more than 2 mo [Widdows et al. 1984], although Hawkins and Bayne [1992] have suggested a period of less than 2 mo). The aim of the present study was to determine the extent to which differences in the feeding regime and the regime of immersion-emersion in their original habitats (rocky shore and collector ropes) affects the behavior of CR and IR during the cultivation period in the raft (20–60-mm shell length). The study also deals with a set of factors, such as an endogenous factor (i.e., shell length) and the environmental and nutritional conditions in the cultivation area, and the effect they have on these physiological rates for raft-cultivated mussels.

MATERIALS AND METHODS

Harvesting and Maintenance of Mussels

In November 1995, seed of *Mytilus galloprovincialis* of approximately 20 mm in length was gathered from the rocky shore and from collector ropes on a raft, both in the mid to outer area of the Ría de Arousa (Galicia, northwest Spain). Both types of seed, from the same year class, came from a spawning period in the previous spring/summer. Experimental cultivation, which was carried out under production conditions on the raft (500 m^2), began in winter—the season of minimal growth rate—with the aim of minimizing any possible advantages for the collector rope seed as a result of its better adaptation to raft cultivation conditions. The experiment continued until July 1996 (226 days) and covered the first stage of mussel cultivation from seeding to thinning out (50–60 mm). Sixteen cultivation ropes (12 m) were used, 8 for each type of seed, disposed alternately and with a density of 19 kg of seed per rope (1.6 kg/m of rope or 2,600 individuals/m of rope). Specimens were sampled each time from adjacent ropes from the stretch of 2–5 m.

The initial length of the seed was 22.55 ± 1.55 mm for collector rope seed and 19.02 ± 1.93 mm for the rocky shore seed. Mean total dry weight was 0.36 ± 0.06 and 0.27 ± 0.06 g/individual for each type of seed, respectively. These differences in length and dry

*Corresponding author. E-mail: mjreiriz@iim.csic.es

weight between the mussels from the two different original habitats were found to be not significant at the beginning of the experiment (analysis of variance [ANOVA]; $P > 0.05$ in both cases; $n = 96$).

Experimental Design

Seawater was pumped from the depth where seed was sampled (2–5 m) into an open circuit consisting of three rectangular cages (45 × 40 × 14 cm = length × width × height and 19 L of capacity), each provided with 16 compartments set in parallel. Seed specimens from the two origins were placed in the side cages while the middle cage, containing no specimens, acted as the control. The water flowed independently into each cage from an inlet pipe, which went all the way around the top of the cage. The water outlet for each cage consisted of a single pipe leading off from the top of the cage. The flow in each cage was maintained at a steady rate of approximately 3 L/min, so that the concentration of particles at the outlet would never fall below 50% of that at the inlet. The number of specimens used in each replica for physiological measurements varied according to their size (i.e., with the length of cultivation period). At the outset, six specimens of the 20-mm shell length class were placed in each compartment, and this number was also used for 30-mm shell length. From the 40-mm shell length onward, the number of animals used progressively decreased and at the end of the experiment there was only one specimen of the 60-mm length class in each compartment. Physiological measurements were taken weekly from November to January, fortnightly from February to May, and monthly in June and July.

Measurements

Natural seston was characterized as total particulate matter (TPM, mg/L), particulate organic matter (POM, mg/L), particulate inorganic matter (PIM, mg/L), particulate volume (Vol, mm^3/L), and chlorophyll *a* (chl-*a*, μg/L). The values for chl-*a*, as well as for the temperature (°C) and salinity (‰) of the water column were provided by the Centro de Control de Calidade do Medio Mariño da Consellería de Pesca, Marisqueo e Acuicultura (Xunta de Galicia). chl-*a* was calculated from the fluorescence data. Seston quality was expressed as Q_1 (POM/TPM), Q_2 (POM/Vol), and the chl-*a*/TPM index. The same methodology as that used for gravimetric analysis of seston was applied to characterize the feces produced by the mussels in the experimental system: seawater samples and aliquots of known volumes from each fecal sample were filtered onto pre-ashed (450 °C for 4 h) and weighed GFC filters and rinsed with isotonic ammonium formate (0.5 M). Total dry matter was established as the weight increment determined after drying the filters to constant weight at 110 °C for 12 h. Organic matter corresponded to the weight loss after ignition at 450 °C for 4 h in a muffle furnace. Vol/L of seawater was determined by counting in the range of 2–56 μm using a Coulter Counter Multisizer II fitted with a 100-μm aperture tube. The variation in these environmental and/or nutritional parameters over the cultivation period is shown in Table 1.

The egestion rates of inorganic matter (mg/h) were determined for each group of mussels and assumed to represent inorganic IR (i.e., no absorption of ash in the digestive tract was considered). CRs were then estimated indirectly, with PIM concentration (mg/L of seawater) as the reference for available inorganic matter: then $CR\ l\ h^{-1}$ = mg $PIM_{Feces}\ h^{-1}$/mg $PIM_{Food}\ L^{-1}$ (Iglesias et al. 1996; 1998), where PIM_{Feces} is the amount of inorganic content voided with the feces in a given unit of time (h) and PIM_{Food} is the inorganic content of the food in a given unit of volume (L). A lag time of 2 h was allowed between the sampling of seawater and the gathering of feces, to account for the estimated time for intestinal transit for mussels from the Ría de Arousa (Navarro et al. 1991). Before the start of the experiments, mussels were kept in the cages for 1 h with flowing seawater at the natural particle concentration to allow for valve opening and acclimation to cage conditions. The feces obtained on the bottom of cages after this time were refused.

The organic ingestion rate (OIR mg org/h) was calculated as a product of CR and the organic food concentration (mg POM/L).

For purposes of comparison with this indirect CR estimation, CR was also calculated by the direct estimation (flow method) using the Hildreth and Crisp (1976) equation: $CR = f([C_i - C_o]/C_m)$, where f is the flow rate, C_i and C_o are food concentrations at the inflow and outflow of the experimental cage, and C_i represents the particle concentration surrounding the mussel. The experimental design used in this study enabled us to consider C_m concentration as being close to C_i, so C_i was subsequently used as the reference concentration for calculation purposes. C_i and C_o were determined by recording the concentration of particles 2–56 μm in water samples with a Coulter Counter Multisizer.

The degree of correlation obtained between the two calculations for CR was highly significant for both groups of mussels together, similar to those observed by Urrutia et al. (1996) and Iglesias et al. (1998) (Y [biodeposition] = 1.118 ± 0.074 × flow + 0.043; $r^2 = 0.86$; $P < 0.001$; $n = 300$). Once significant relationships were established for both methodologies, CR here (text, tables, and figures) refers to indirect measurements by biodeposition method.

Size Standardization

To preclude variability in physiological rates caused by size differences, these rates were corrected to a standard-sized individual. To this end, once physiological measurements were completed, shell length of each individual was recorded to the nearest 0.1 mm with Vernier calipers and the soft tissues excised from the shell, dried at 110 °C for 12 h, and weighed. The most commonly used reference for size is soft body mass; however, the weight standardization of CR may be somewhat arbitrary, because this rate is considered to be dependent on filtration (gill) area, which is closely related to shell length (Hughes 1969; Jones et al. 1992). As discussed before by Iglesias et al. (1996) and Labarta et al. (1997), in this study we used shell length (L) to standardize CR following the equation: $Y_s = Y_e \times (L_s/L_e)^b$ where Y_s and Y_e are the standardized and the nonstandardized CRs, respectively; L_s is the standard length of the animal according to shell increment during the experiment (20–60 mm); L_e is the observed length of the animal; and b is the power that scales CR with shell length (b = 1.85, Pérez Camacho and González 1984). Furthermore, with the aim of establishing the fluctuation of clearance and IRs over the cultivation period, 40-mm shell length was chosen as an average size for the experiment.

Data Analysis

Comparison of means for CR and OIR was carried out by means of standard ANOVA after data transformation when necessary. Kruskall-Wallis and Friedman nonparametric tests were used when homogeneity was lacking (Bartlett's test). Multiple analysis (stepwise regression) was used to determine the effect of

TPM, total particulate matter; POM, particulate organic matter; PIM, particulate inorganic matter; Vol, total particulate volume; Chl-*a*, chlorophyll-*a*; Q_1, relative organic content (by weight); Q_2, relative organic content (by volume); Chl-*a*/TPM, relative chlorophyll-*a* content (by total particulate matter).

various factors, both endogenous (shell length) and environmental (TPM, POM, Vol, Q_1, Q_2, T, and chl-*a*), and their interactions on the variation in CR. The factor seed origin was added to this analysis with values of 0 and 1 for collector rope and rocky shore mussels, respectively. All of these analyses were performed according to the methods described by Snedecor and Cochran (1980) and Zar (1984).

RESULTS

The values of CR and OIR during the experiment are shown in Table 2. CR ranges between 0.20 and 0.26 L/h in the initial stages of cultivation (20-mm mussel), rising up to 4.37–4.51 L/h for a 60-mm mussel.

CR values for collector rope mussels were significantly higher than those of rocky shore mussels in days 0 and 8 of the experimental period ($P < 0.01$ in both cases; ANOVA; Table 2). However, CR for the rocky shore mussels had increased by 35% by the end of the 2nd week, compared with only 16% for the collector rope specimens. From this point on, no further significant difference in this physiological rate was recorded between the two types of mussels ($P > 0.05$; Table 2). In the case of OIR, both groups of mussels followed the same pattern as that described for CR (Table 2).

VARIATION OF CR AND OIR IN CULTIVATION TIME

Figure 1 shows the variation of standardized CR and OIR for the 40-mm length class in cultivation time. CR showed a clear seasonal pattern with low values during the winter months, increasing in spring and summer. High values recorded in January constituted the sole exception. These trends were also recorded for OIR (Fig. 1), amplified in this case by the coincidence of high CR and high POM.

CR versus Shell Length and Environmental Parameters

The multiple regression analysis carried out on the variation observed in CR during the experiment showed a significant and positive relation to size (L mm), food quality (Q_1), and temperature (see F-ratio, Table 3). The regression model accounted for 76.7% of the variance for CR, which in turn is mainly accounted for by size (L mm 67.6%), with a coefficient of 1.762. It is important to point out the significant negative effect of the interactions of food quality (Q_1) with both origin ($Q_1 \times$ origin) and temperature ($Q_1 \times T$) (Table 3).

Organic IR versus Natural Seston (TPM mg/L)

A significant relationship was established between the IR (OIR) and the variation in seston (TPM, mg/L), that could not be established in the case of the CR. This response of ingestion to seston concentration is shown in Figure 2 and fits exponential functions according to the Ivlev curves $IR = a\,(1 - e^{b \cdot TPM})$:

Collector ropes

$$OIR = 1.29 \pm 0.39\,[1 - e^{-0.75 \pm 0.36 \cdot TPM}]$$
$$n = 14;\ r^2 = 0.517;\ P < 0.01$$

Rocky shore

$$OIR = 1.18 \pm 0.36\,[1 - e^{-0.87 \pm 0.46 \cdot TPM}]$$
$$n = 14;\ r^2 = 0.481;\ P < 0.01$$

The covariance analysis performed for the linear transformations of these exponential curves showed no significant differences

CR, clearance rate length-specific (L/h) by biodeposition method; OIR, organic ingestion rate length-specific (mg POM/h).
* $P < 0.01$, †$P < 0.05$, ANOVA and Kruskall-Wallis nonparametric test in case of heterogeneity of variances).

between both groups of mussels for OIR ($t = 0.037$, $df = 24$, $P > 0.05$, and $t = 0.358$, $df = 25$, $P > 0.05$ for analysis of slopes and intercepts, respectively). Therefore, one exponential curve for both groups of mussels together is shown in Figure 2:

$$OIR = 1.23 \pm 0.26\,[1 - e^{-0.78 \pm 0.26 \cdot TPM}]$$
$$n = 28;\ r^2 = 0.500;\ P < 0.01$$

DISCUSSION

The variation in CR and OIR during the experimental period, for mussels standardized to 60 mm to compare with the literature values, covers a wide range (1.46–4.51 and 1.13–4.37 L/h for CR, 0.43–2.23 and 0.33–2.04 mg POM/h for OIR, values for collector rope and rocky shore mussels, respectively). These data coincide with those obtained by Navarro et al. (1991) and Iglesias et al. (1996) for *M. galloprovincialis* in the Ría de Arousa. In the case of CR, however, these values are higher than those recorded for mussels elsewhere reported by Okumus and Stirling (1994) in their wide-ranging review. Despite the above-mentioned differences in CR due to low seston loads, characteristics from Galician Rias in particular, the values for organic IRs reported in the present study are similar to those obtained by Widdows et al. (1979), also under environmental conditions, and by Bayne et al. (1989) in the laboratory, with a higher range of values for seston and organic content (0.79–7.43 mg TPM/L, 0.43–1.79 mg POM/L, and 0.18–0.71 for Q_1).

The few studies that include CR data recorded over a period of seasons show that CR follows a clear seasonal pattern, with maximum values occurring in the spring and summer months and minimum values in winter. This cycle can be observed both under laboratory conditions, with a constant food supply available (Worrall et al. 1983), and under natural conditions (Newell and Bayne 1980). Larretxea (1995), taking into account a previous study of Hawkins et al. (1985), suggests that the seasonal sequence of CR is persistent to a large extent, although the effect of temperature could be an important determinant of this seasonal response.

In this study, rates of energy acquisition exhibit a seasonal pattern, with lower values occurring during the winter months and slightly higher during spring and summer. The range results greater in terms of OIR because of the simultaneous decrease in CR and in organic content of the seston. An exception to this overall behavior are those values found to deviate largely from the mean of the season during which they were obtained, namely unexpectedly high values for CR, and especially OIR, in the samples taken in January. These may be accounted for by the high

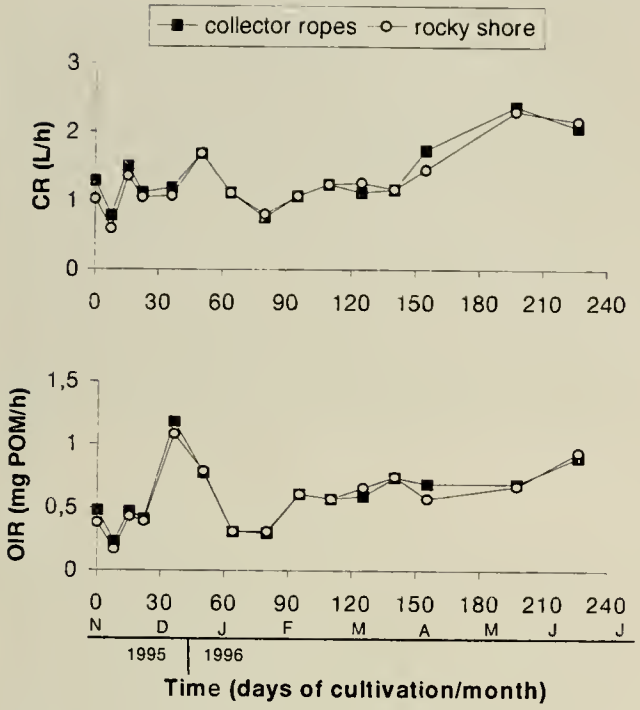

Figure 1. Seasonal changes in CR and OIR standardized to 40 mm of shell length for both sources of seed mussel *M. galloprovincialis*.

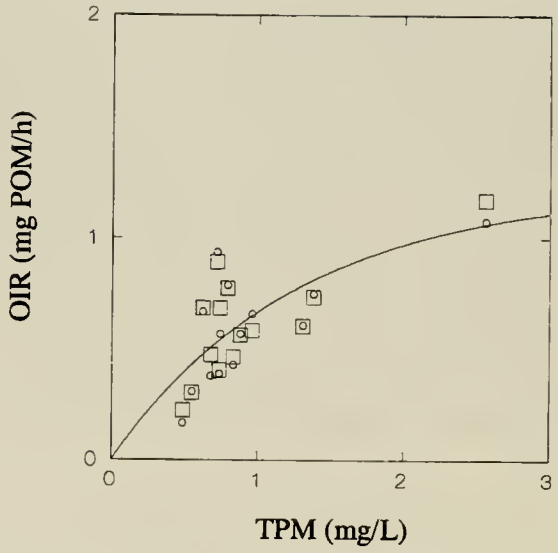

Figure 2. OIR versus TPM relationship for both sources of seed mussel *M. galloprovincialis*. Both groups of mussels (collector ropes, squares; rocky shore, circles) were fitted by nonlinear regression according to Ivlev curve: $Y = a(1 - e^{b \cdot X})$ (see text for details of fitting equation).

POM values (1.003 mg/L) and high Q_1 value (0.586), which can be considered as a result of a process of resuspension of material from the bottom in the Ria de Arousa (Babarro et al. 2000). Similar feeding behavior has been observed by Kiørboe et al. (1981) and Larretxea (1995) concerning CR increments associated with an increase in detritus and sediment resuspended.

With regard to seston composition, the results of this study show a 33% increase in total organic content in spring/summer when compared with winter, which can be related to an increase in mean CR of 30% for collector rope mussels and 40% in the case of rocky shore specimens.

However, other factors that seem to exert indirect influence on the energy gain should be taken into account. This is the case for chl-*a* values for the period February through July that doubles that of the period November through February (Babarro et al. 2000). During the winter months, the proportion of phytoplankton (chl-*a*) in the organic content of the diet is 4–23%, rising to 21–41% during spring and summer, with peaks of 37.4% and 40.9% in April and February, respectively, which bears a close relationship to the seasonal variation in CR and OIR (carbon content = chl-*a* × 54, Widdows et al. 1979; organic matter = carbon × 1.87, Fernández Ríos 1992). This incidence of phytoplankton (chl-*a*) can also be observed in the fact that when the value for POM is not associated with chl-*a* (Babarro et al. 2000), no effect on CR is observed. However, the effect of this factor (chl-*a*) has not been tested in the multiple model because of the use of Q_1 as a factor of food quality and in order to avoid overlapping of information.

TABLE 3.

Stepwise multiple regressions of clearance rate of mussels with log shell length (L), quality of seston (Q_1 = POM/TPM), temperature (T, °C), and interactions terms.

$r^2 = 0.767$; $n = 812$; $F_{6,805} = 440.729$; $P < 0.001$

Origin factor has been estimated with values 0 and 1 for collector ropes and rocky shore mussels, respectively.

The multiple regression model for CR shows the importance of shell length, food quality (Q_1), and the temperature either as an independent variable or as a term in interaction ($Q_1 \times T$). Very likely the presence of a term $Q_1 \times$ origin could be related to differences in seston quality between both original locations. Previous studies carried out with both groups of mussels showed higher Q_1 values for subtidal location than that for rocky shore (unpublished data). Shallow water and stronger tidal waves in the rocky shore spot seem to affect the relation organic:inorganic fraction, with resuspension processes of the sediment playing an important role. Mussels seem to adjust their feeding rates in a relatively short time under environmental changes (first 8 days under culture conditions), and probably when animals are "adapted," fluctuations of Q_1 after this initial period of time do not cause different CR responses between the two populations.

The effects of the food ration or particle concentration on filtration rates in bivalve molluscs have been widely studied over the years. A reduction in CR when seston concentration increase has been reported in several experiments (Foster-Smith 1975; Widdows et al. 1979; Riisgård and Randløv 1981). As was previously established by Winter (1978), it seems that the ability of bivalves to adjust CR in response to an increase in particle concentration allows the regulation of IR.

In fact, the relationship between IR and seston concentration has been appropriately described by an exponential asymptotic

function (Ivlev curve) in this study. This behavior suggests to us a mechanism of regulation of ingestion based, in this case, on adjusting CR and taking into account that this saturating increase in OIR cannot be assigned to the negative organic content versus seston availability relationship, which was not observed in our study as significant. Although higher CRs are related with lower seston availability values, significant effects of either TPM or POM and chl-*a* on CR were not observed, possibly because of the reduced range of variation in seston concentration.

As already been mentioned, the results of this study establish that temperature has a significant effect on CR. The thermodependence of CR coincides with the observations made by Widdows (1976), namely that mussels living in a stable thermal environment (which is the case with a range of temperature variation of 2.73 °C) have not developed compensation mechanisms, being thermodependent.

Although the effects associated with origin have been considered by many authors to be indicative of genetic differences between mussels from different original habitats, Mallet et al. (1987) offered an alternative explanation. In their study, the authors suggested that these effects would reflect the differential influences undergone by mussels during their pre-experimental stage, so conforming to an "ecological memory" of the individuals with respect to the conditions experienced in the primary habitat (food availability and quality, tidal regime, air exposure, etc.). Okumus and Stirling (1994), Navarro et al. (1996), Iglesias et al. (1996), and Labarta et al. (1997) all recorded differences in CR for mussels from different original habitats, which they attribute to this ecological memory.

The present study shows significant differences for CR and OIR between different original habitats of the mussels (collector rope and rocky shore) at the outset of the experiment that persisted after 8 days' cultivation on the raft. These significant differences concerning the two physiological rates between both types of mussel disappeared 15 days after raft cultivation commenced. The initial differences in CR and OIR may be the consequence of a response by the rocky shore mussels to the new conditions found on raft cultivation (i.e., a lower concentration and higher-quality Q_1 of seston in continuous immersion; previous data unpublished) over a short period of time. This hypothesis is supported by results of the multiple regression analysis, which indicates that both Q_1 and origin, the latter being expressed as a term of interaction with Q_1, account for a part of the variance experienced by CR according to the model.

ABSTRACT The nonindigenous brown mussel *Perna perna* was first recorded in the Gulf of Mexico at Port Aransas, Texas in 1990. The association between survival time and chronic exposure to hypo- and hypersaline conditions was examined to estimate the potential range of habitats that *P. perna* could invade in coastal North American Gulf of Mexico habitats. A novel application of the discrete logistic failure time model (DLFTM) was used to estimate covariate-adjusted median survival times from the interval-level survival data collected. This method allowed factorial-type comparisons of the covariate-adjusted medians across treatments. This analysis indicated that salinities ranging from 15–50 ppt are nonlethal to *P. perna*, under which at least 80% of individuals survived 30 days (720 h). Chronic exposure to salinities outside 15–50 ppt were lethal to *P. perna*. Lethality was size-dependent, with both smaller and larger individuals having reduced survival times. For an average-sized individual (shell length = 40 mm), median survival times were 191, 268, 335, 119, and 116 h at 0, 5, 10, 55, and 60 ppt, respectively. The 15–50 ppt incipient salinity limits of Texas *P. perna* suggest that this species could potentially colonize the majority of marine and estuarine coastal habitats in the Gulf of Mexico.

KEY WORDS: interval-level survival data, mytilacea, nonindigenous species, *Perna perna*, salinity tolerance

INTRODUCTION

Since its initial discovery in Port Aransas, Texas, in 1990, the marine brown mussel, *Perna perna* (L.), has colonized hard shores at intermittent locations throughout the southwestern Gulf of Mexico in Texas and Mexico (Hicks and Tunnell 1993, Hicks and Tunnell 1995). The majority of the Gulf of Mexico's margins are sandy beaches, which has historically impeded development of natural hard-shore communities. Thus, it was not until the construction of jetties, breakwaters, and other coastal structures during the last century that habitat existed for true intertidal bed-forming mytilid genera such as *Perna*. These man-made structures, which are continuously being constructed to control coastal erosion, present a relatively open niche for such invasive mytilid species as *P. perna*. Generally, considered an open-water species (Berry 1978), Texas *P. perna* populations have been reported from littoral and shallow sublittoral habitats of widely varying physiochemical parameters including the low salinity (20–25 ppt) Lavaca-Tres Palacios estuary (Davenport 1995) and the hypersaline (35–40 ppt and occasionally higher) Laguna Madre (McGrath et al. 1998).

The endemic range of *P. perna* (synonymous with *Perna picta* (Born) and *Perna indica* Kuriakose and Nair, [Siddall 1980, Vakily 1989]) includes India, Sri Lanka, Madagascar, the east coast of Africa from central Mozambique to False Bay, South Africa, and the African west coast from Luderiz Bay, Nambia, north into the Mediterranean from Gibraltar to the Gulf of Tunis as well as on the Atlantic coasts of Brazil, Uruguay, Venezuela, and in the West Indies (Berry 1978).

Salinity influences many physiological functions, making it an important limiting factor in the distributions of estuarine and marine bivalves (Bayne et al. 1976, Widdows 1985, Dame 1996). As with most marine mytilaceans, *P. perna* is incapable of extracellular osmotic control; thus, its extracellular fluids are nearly isosmotic to ambient seawater over its tolerated salinity range (Salomão and Lunetta 1989). The typical short-term response of osmoconforming bivalves to salinity reductions is to close the shell valves temporarily isolating tissues and body fluids from potentially lethal hyposaline waters, while allowing time for intracellular volume regulation by adjusting the concentrations of intracellular amino acids and other small organic molecules (Hawkins and Bayne 1992).

We examined the effects of chronic exposure to hypo- and hypersaline media on survival times in *P. perna*. Salinity tolerance data have proved effective in predicting local distributions in marine bivalves (Castagna and Chanley 1973). Thus, the incipient salinity limits determined in this study were used to predict the potential for *P. perna* to colonize coastal Gulf of Mexico marine and estuarine habitats in North America.

We also developed a specialized methodology for analyzing our survivorship data that allows estimating and comparing covariate-adjusted median survival times for grouped lifetime data. Current methods for analyzing data of this type compare treatment survival distributions based upon odds-ratios. Our method of using median survival times, as opposed to odds, provides biologically more meaningful interpretations of survival data.

MATERIALS AND METHODS

Experimental Protocol

Specimens of *Perna perna* were collected from intertidal rocks on the north jetty of Mansfield Pass (26 °34 ′N) on the Texas coast and were transported overnight in cooled insulated containers to Arlington, Texas. Upon arrival, mussels were maintained in a 284-L aerated holding tank containing artificial seawater (35 ppt) at a constant temperature of 20 °C on a 12:12 hour light–dark cycle without feeding before experimentation. Experiments were initiated within 30 days of collection.

Individual mussels were excised from mussel clumps by cutting byssal attachment threads with scissors before salinity tolerance testing. For each salinity tested, four subsamples of 10 mussels each, visually selected to be of similar size range, were held for 2 weeks in a constant temperature laboratory at 20 °C (±1 °C) in 3.5-L plastic aquaria containing 3 L of continuously-aerated, 35 ppt artificial sea water (Fritz Supersalt). Tank medium was replaced daily. During the 2 week acclimation period, mussels byssally reattached to tank walls or other individuals. The size range of the subsamples utilized in each salinity test reflected the size range in the original sample (shell lengths ~ 15–70 mm).

After acclimation to experimental conditions, subsamples were randomly assigned to test salinities of 0, 5, 10, 15, 20, 30, 40, 50, 55, and 60 ppt (created with Fritz Supersalt and City of Arlington, Texas, dechlorinated tap water), chosen to include the range of salinities occurring in Texas coastal aquatic habitats. Testing was initiated by replacing the 35 ppt seawater medium in each tank with 3 L of test salinity medium. During testing, media were held at 20 °C (±1 °C), continuously aerated and changed daily. Byssal attachment, valve opening or closure, and viability of all individuals was examined at 24-h intervals. Viability was determined by touching the exposed mantle edges of emersed gaping mussels with the tip of a fine-haired brush. Individuals not closing their valves in response to this stimulus were considered dead, and were removed from the aquaria. The time of the observation was recorded, and the shell lengths (SL) of dead individuals were measured as the linear distance from the anterior to posterior margins of the shell to the nearest 0.1 mm using digital calipers. All nongaping individuals were considered alive. Exposure to salinity treatments and viability testing was continued until either 100% sample mortality was achieved or individuals survived for 30 days (720 h).

Statistical Methods

The salinity resistance of specimens of *P. perna* was examined using a survival analysis strategy designed to determine the effects of seawater concentration on survival duration; whereas, controlling for individual-specific covariates (e.g., size). Our viability monitoring at 24-h intervals prevented knowledge of an individual's exact time of death. Thus, survival time was known only to fall within the interval $I_j = [a_{j-1}, a_j]$, while a_j was the current observation time, and a_{j-1} was the last observation time. Available parametric (e.g., Weibull) and nonparametric (e.g., Kaplan-Meier, Cox regression) survival estimation methods assume that the time of death is known exactly. However, in the vast majority of such studies, as in this one, time of death is not recorded exactly, but is known only to have occurred within a particular interval (Hosmer and Lemeshow 1989). Applying continuous-data methodology to such interval-level data can result in serious bias, especially if the interval length is large relative to the average lifetimes one is observing.

When survival data are recorded at the interval level, the life table (i.e., actuarial method) is often used to estimate survival probabilities. Life tables are essentially frequency tables modified to deal with censored observations (i.e., those data for individuals that survive treatments) (Lawless 1982). The main outcome of life table analysis is estimation of the survival function $S(a_j)$, which is the probability of surviving to time a_j, for all observation times $a_1, \ldots, a_k$. However, standard life table analysis cannot incorporate continuous regressors, such as size, which are likely to influence individual survival times. When such regressor variables are present, a discrete logistic failure time model (DLFTM), which generalizes the life table method, can be used to estimate survival probabilities and allow their adjustment for regressor effects (Cox 1972, Thompson 1977). The ability to include regressor variables in the DLFTM greatly broadens the scope of life table analysis by revealing both treatment and individual-specific regressor influences, allowing more biologically appropriate interpretations of survival data (Lawless 1982, Hosmer and Lemeshow 1989).

Although survival probabilities, when graphed into the usual form of survival functions, provide a summary of the survival experience of a population, these functions are cumbersome when there are many such populations to be compared (e.g., levels of treatments, different values of important regressors). In such cases, it is useful to have a one-number summary (e.g., the median survival time) of each survival function to compare across many populations. The DLFTM can, as illustrated here, be used to provide such median estimates for interval level data under some reasonable assumptions discussed below.

We implemented the DLFTM for our data analysis in a computer program written in SAS's interactive matrix language (IML, SAS, Cary, NC) available from the authors. The routine was checked for programming errors using simulations of data from lifetime distributions with known parameters.

DLFTM and Its Estimation

For our analysis, the 720-h observation period was divided into 24-h time intervals, $I_j = [a_{j-1}, a_j)$, $j = 1, \ldots, k = 30$, where $a_j = 24 \cdot j$ are times of observation, $a_0 = 0$ and $a_{k+1} = \infty$. The data for the ith individual, $1 \le i \le n$, consists of the vector $\mathbf{G}_i = (G_{i1}, \ldots, G_{i,k+1})$, where $G_{ij} = 1$ if individual i dies in interval I_j and $G_{ij} = 0$ otherwise, and a vector $\mathbf{x}_i$ of covariates describing treatments and individual-specific characteristics.

Let T_i denote the actual, but unobserved, lifetime of individuals. Let $S(t \mid \mathbf{x}) = \Pr(T_i > t \mid \mathbf{x})$ denote the survival function of individuals with regressor $\mathbf{x}$, which contains indicator variables describing salinity level and shell length (SL). The goal of the analysis was to estimate the survival probabilities $\underline{P}_j(\mathbf{x}) = S(a_j \mid \mathbf{x})$ at each of the observation times $a_1, \ldots, a_k$. By a standard argument using conditional probabilities (see Lawless 1982, p. 55),

$$\underline{P}_j(\mathbf{x}) = p_1(\mathbf{x}) \cdots p_j(\mathbf{x}), \quad 1 \le j \le k, \tag{1}$$

where $p_j(\mathbf{x}) = \Pr\{T_i \ge a_j \mid T_i \ge a_{j-1}, \mathbf{x}\}$ is the probability of surviving the time interval I_j, given alive at its outset. The $p_j(\mathbf{x})$s are called "interval-specific" survival probabilities. It is clear from (1) that to estimate $\underline{P}_j(\mathbf{x})$ it is enough to estimate the $p_j(\mathbf{x})$s.

The method of maximum likelihood estimation was applied to estimate the $p_j(\mathbf{x})$s, because it is known to produce estimates statistically optimal for large sample sizes n. In this regard, again by

a standard argument (see Lawless 1982, p.372), the likelihood function for the above data on n independent individuals, assuming censoring only at a_k, is

$$L[p_1(\bullet), \ldots, p_k(\bullet)] = \prod_{j=1}^{k} \left\{ \prod_{i \in D_j} [1 - p_j(\mathbf{x}_i)] \cdot \prod_{i \in R_j - D_j} p_j(\mathbf{x}_i) \right\} \quad (2)$$

where: R_j is the set of individuals i who are alive just before a_{j-1}, and D_j is the set of individuals i who die in interval I_j.

The DLFTM is a model for the functional form of $p_j(\mathbf{x})$. Specifically,

$$p_j(\mathbf{x}) = (1 + e^{\alpha_j + \mathbf{x}\boldsymbol{\beta}})^{-1}, \; 1 \le j \le k, \quad (3)$$

where $\boldsymbol{\beta} = (\beta_1, \ldots, \beta_m)^T$ is an $m \times 1$ vector of unknown regression coefficients relating the covariate vector $\mathbf{x} = (x_1, \ldots, x_m)$ to p_j, and the a_js are interval-specific parameters (i.e., the interval effects). Because (3) implies

$$\frac{1 - p_j(\mathbf{x} + \Delta)}{p_j(\mathbf{x} + \Delta)} = e^{\Delta\boldsymbol{\beta}} \left[\frac{1 - p_j(\mathbf{x})}{p_j(\mathbf{x})} \right], \; 1 \le j \le k \quad (4)$$

for any Δ, it follows that $\boldsymbol{\beta}$ relates the odds of death in any interval I_j for covariate value $\mathbf{x} + \Delta$ [i.e., the left side of (4)] to the odds of death in I_j for covariate value $\mathbf{x}$. Thus, if $\beta_r > 0$ (<0) for some $1 \le r \le m$, the odds of dying in interval I_j increases (decreases) as x_r increases. The parameter α_j is seen from (3) to equal $\ln\{[1 - p_j(0)]/p_j(0)\}$, the log-odds of death in interval I_j when $\mathbf{x} = 0$.

For a particular choice of the covariate vector $\mathbf{x}$ (i.e., including terms to represent treatments, dependence on SL, etc.), the unknown parameters $\boldsymbol{\beta}$ and $\boldsymbol{\alpha} = (\alpha_1, \ldots, \alpha_k)^T$ in the DLFTM (3) are estimated by substituting (3) into the likelihood (2), and then maximizing the resulting "constrained likelihood" (5) with respect to $\boldsymbol{\beta}$ and $\boldsymbol{\alpha}$ (Lawless 1982).

$$L(\boldsymbol{\alpha}, \boldsymbol{\beta}) = \prod_{j=1}^{k} \left[\left(\prod_{i \in D_j} \left\{ \frac{e^{\alpha_j + \mathbf{x}_i\boldsymbol{\beta}}}{1 + e^{\alpha_j + \mathbf{x}_i\boldsymbol{\beta}}} \right\} \right) \left(\prod_{i \in R_j - D_j} \{1 + e^{\alpha_j + \mathbf{x}_i\boldsymbol{\beta}}\}^{-1} \right) \right]. \quad (5)$$

The logarithm of this constrained likelihood is

$$\log L(\boldsymbol{\alpha}, \boldsymbol{\beta}) = \sum_{j=1}^{k} \left[\sum_{i \in D_j} (\alpha_j + \mathbf{x}_i\boldsymbol{\beta}) - \sum_{i \in R_j} \ln(1 + e^{\alpha_j + \mathbf{x}_i\boldsymbol{\beta}}) \right]. \quad (6)$$

The maximum likelihood estimators (mles) $\hat{\boldsymbol{\alpha}}$ and $\hat{\boldsymbol{\beta}}$ of $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$ are obtained by maximizing (6). The maximization is done by the Newton–Raphson algorithm, which iteratively solves the so-called likelihood equations (writing $\mathbf{x}_i = (x_{i1}, \ldots, x_{im})$)

$$\frac{\partial \log L}{\partial \beta_r} = \sum_{j=1}^{k} \left(\sum_{i \in D_j} x_{ir} - \sum_{i \in R_j} \frac{x_{ir} e^{\alpha_j + \mathbf{x}_i\boldsymbol{\beta}}}{1 + e^{\alpha_j + \mathbf{x}_i\boldsymbol{\beta}}} \right) = 0, \; r = 1, \ldots, m; \text{ and} \quad (7)$$

$$\frac{\partial \log L}{\partial \alpha_v} = \sum_{i \in D_v} (1) - \sum_{i \in R_v} \frac{e^{\alpha_v + \mathbf{x}_i\boldsymbol{\beta}}}{1 + e^{\alpha_v + \mathbf{x}_i\boldsymbol{\beta}}} = 0, \; v = 1, \ldots, k. \quad (8)$$

The interval-specific survival probability estimates, $\hat{p}_j(\mathbf{x})$ are obtained by substituting the *mle*s, $\hat{\boldsymbol{\alpha}}$ and $\hat{\boldsymbol{\beta}}$ into (3). The survival probability estimates $\hat{\underline{P}}_j(\mathbf{x})$ are then obtained by plugging the $\hat{p}_j(\mathbf{x})$ into (1). The issue of which variables to include in the regressor vector $\mathbf{x}$ (e.g., linear or quadratic functions of SL, treatment by SL interactions, etc.) was addressed by beginning with a model a priori deemed sufficiently flexible and then testing a sequence of nested models until reaching the most parsimonious model that adequately explained the data. Goodness-of-fit was assessed by comparing the most parsimonious fitted model to the a priori model (i.e., the model containing at most quadratic functions of SL and treatment by SL interactions) by a Wald statistic.

To conduct inferences using the estimated $\hat{\underline{P}}_j(\mathbf{x})$s, their covariance matrix was needed. This matrix was derived by a sequence of three steps, the first of which was to construct the covariance matrix of the estimators $\hat{\boldsymbol{\alpha}}$ and $\hat{\boldsymbol{\beta}}$. An estimate of the covariance matrix of $\hat{\boldsymbol{\theta}} = (\hat{\boldsymbol{\alpha}}, \hat{\boldsymbol{\beta}})$ was obtained as the negative of the inverse of the matrix of the second-order partial derivatives of $\log L$ (6) (i.e., $-H^{-1}$, where H is the Hessian matrix). The covariance matrices of the derived estimates $\hat{p}_j(\mathbf{x})$ and $\hat{\underline{P}}_j(\mathbf{x})$ were propagated, in turn, from the covariance matrix of $\hat{\boldsymbol{\theta}}$ by the Delta method (Serfling 1980). See Appendix A for details.

Estimating Median Survival Time

A unique aspect of our application of the DLFTM to analyze salinity as a lethal factor in *P. perna* was our incorporation of a method of estimating, and computing variances for, the covariate-adjusted median survival times. This method allows factorial-type comparisons of the covariate-adjusted medians across treatments. Median survival time, $M(\mathbf{x})$, which satisfies $S(M(\mathbf{x})|\mathbf{x}) = 0.5$, was estimated by assuming that the survival function, $S(t|\mathbf{x})$, was linear in t (for fixed $\mathbf{x}$) over each time interval $[a_{j-1}, a_j)$. Specifically, given that $\hat{\underline{P}}_j(\mathbf{x}) < 0.5 \le \hat{\underline{P}}_{j-1}(\mathbf{x})$ for some $1 \le j \le k$, then the median estimate is (using linear interpolation)

$$\hat{M}_j(\mathbf{x}) = a_j + \left[\frac{a_j - a_{j-1}}{\hat{P}_j(\mathbf{x}) - \hat{P}_{j-1}(\mathbf{x})} \right] \left[\frac{1}{2} - \hat{P}_j(\mathbf{x}) \right], \quad (9)$$

for the interval index j in which $\hat{P}_j(\mathbf{x}) < 0.5 \le \hat{P}_{j-1}(\mathbf{x})$. However, this interval is itself a random variable, so it is necessary to express the median estimate as

$$\hat{M}(\mathbf{x}) = \sum_{j=1}^{k} \hat{M}_j(\mathbf{x}) I[\hat{P}_j(\mathbf{x}) < 0.5 \le \hat{P}_{j-1}(\mathbf{x})] \quad (10)$$

where $\hat{M}_j(\mathbf{x})$ is given by (10), and the indicator variable [second factor in the summand in (10)] equals 1 if the parenthetical inequality holds and is zero otherwise [note that at most, one of the terms in the sum in (10) is nonzero]. In plain English, this just says to "find the interval j where the survival probabilities $\hat{\underline{P}}_j(\mathbf{x})$ cross 0.5 and use the estimate (9)." Equation (10) defines the estimated median $\hat{M}(\mathbf{x})$ only if $\hat{\underline{P}}_k(\mathbf{x}) \le 0.5$. Otherwise, $\hat{M}(\mathbf{x})$ is undefined.

To obtain $\text{var}[\hat{M}(\mathbf{x})]$ and $\text{cov}[\hat{M}(\mathbf{x}_1), \hat{M}(\mathbf{x}_2)]$ for $\mathbf{x}_1 \ne \mathbf{x}_2$, we again want to appeal to the delta-method, because, as is apparent from (10), $\hat{M}(\mathbf{x}) = G[\hat{\underline{P}}_1(\mathbf{x}), \ldots, \hat{\underline{P}}_k(\mathbf{x})]$ for an albeit complicated function G. However, this approach failed in this case, because the function G is not differentiable with respect to the $\hat{\underline{P}}_j$s [the indicator functions in (10) are discontinuous and, hence, not differentiable, so that the delta method does not apply]. To avoid this problem, we used an approximation method detailed in Appendix B.

By manipulating the regressor vector $\mathbf{x}$, estimates (and their covariance matrix) of covariate-adjusted median survival time were obtained for each treatment combination. Specifically, let M denote the vector of the true median survival times for the various treatments, and for target values of the continuous regressors (e.g., SL). Let $\hat{M}$ denote the corresponding vector of estimates, and let

$\text{Var}(\hat{M})$ denote the covariance matrix of $\hat{M}$ as obtained above. Comparison of median survival times across treatments was carried out via testing hypotheses of the form H_o: $\boldsymbol{CM} = 0$, where $\boldsymbol{C}$ is a hypothesis matrix of coefficients having linearly independent rows, using the Wald statistic

$$W = (\mathbf{C}\hat{\mathbf{M}})^T[\mathbf{C}Var(\hat{\mathbf{M}})\mathbf{C}^T]^{-1}(\mathbf{C}\hat{\mathbf{M}}). \quad (11)$$

Under H_o, the statistic W is distributed approximately chi-square with m degrees of freedom, where m is number of rows in $\mathbf{C}$. Large values of W provide evidence against H_o. Type I error was controlled using the Scheffé method for an experimentwise error rate of $\alpha = 0.05$.

RESULTS

Survivorship in *Perna perna* declined in hyposaline and hypersaline treatments. Salinities ranging from 15–50 ppt appeared nonlethal to this species, with at least 80% of individuals surviving the 30-day (720 h) exposure period. Following the 30-day period, surviving individuals were cut from byssal attachments and transferred back to full-strength seawater and allowed 72 h to reattach. Thereafter, the average number of attached byssal threads per individual and the associated salinity concentration were as follows: 15 (15 ppt), 11 (20 ppt), 13 (30 ppt), 13 (40 ppt), and 8 (50 ppt). The capacity for byssal reattachment indicated that individuals exposed to salinities of 15–50 ppt were not physiologically damaged. In contrast, complete sample mortality was observed at the following times and salinities: 360 h (0 ppt), 408 h (5 ppt), 648 h (10 ppt), 168 h (55 ppt), and 216 h (60 ppt) (Fig. 1).

In the most parsimonious, fitted survival model (Eq. 3), survival was significantly correlated to both SL and SL^2, but the SL effects did not interact with salinity treatment ($\chi^2_{(18)} = 18.7$; $P = 0.412$). Specifically,

$$\log\left[\frac{1 - p_j(\mathbf{x})}{p_j(\mathbf{x})}\right] = \beta_o + \sum_{T=1}^{9}\beta_T I_T + \gamma_1 SL + \gamma_2 SL^2$$

where β, γ_1 and γ_2 are coefficients for treatment and SL, respectively, and I_T is the indicator variable for salinity treatment T (i.e., $I_T = 1$ for salinity treatment T and zero otherwise).

The estimated survival functions [i.e., the linearly interpolated $\underline{\hat{P}}_j(\mathbf{x})$s] for lethal salinity treatments, adjusted to the sample mean SL (40 mm), indicated decreasing survivorship probabilities as salinity concentrations departed from full strength seawater (35 ppt) with those in the most saline treatments (i.e., 55 and 60 ppt) having the lowest median survival times (Fig. 1).

The relationship between survivorship and SL can be shown by using the model to estimate median survival at the 10th, 25th, 50th, 75th, and 90th percentiles of the SL distribution in each salinity treatment. This analysis indicated that intermediate-sized individuals (48 mm SL) had longer survival times (Fig. 2). For an average-sized individual, SL = 40 mm, the median survival times and associated salinity concentrations were as follows: 191 h (0 ppt),

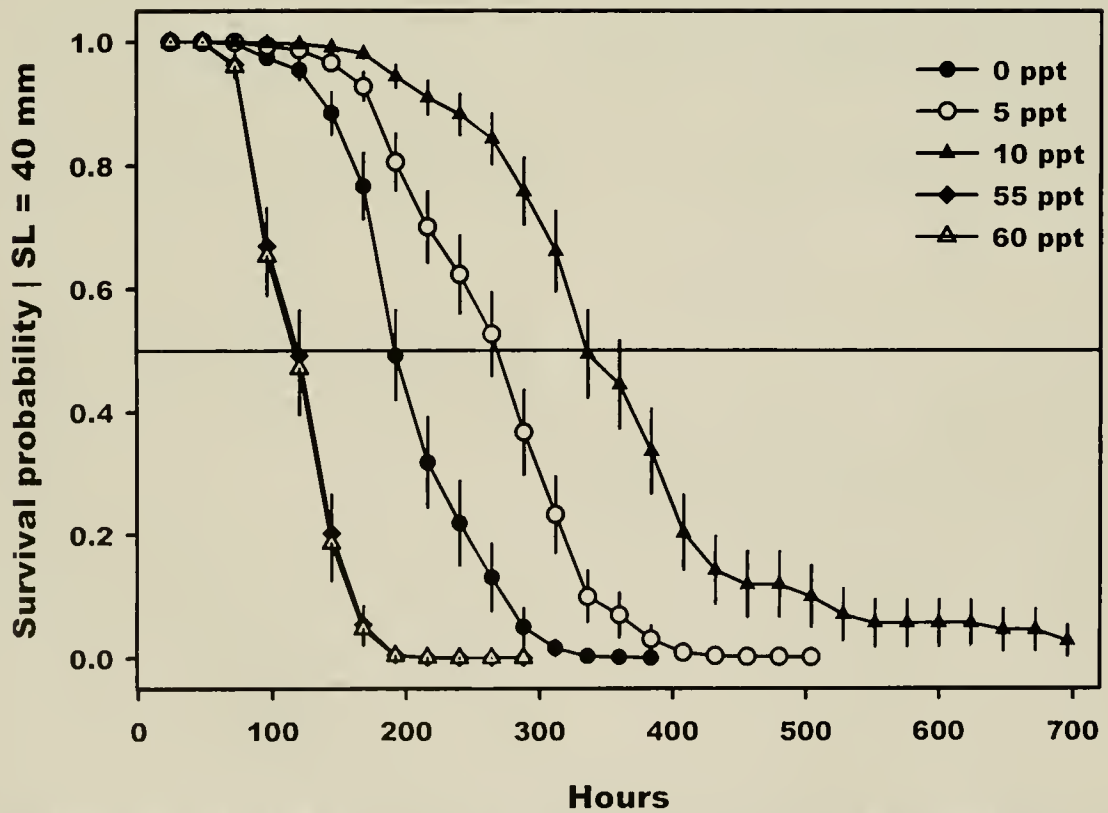

Figure 1. Survivorship curves for standard 40 mm shell length specimens of *Perna perna* chronically exposed to lethal salinity treatments. Lines represent linear interpolations of the cumulative survival probabilities, the $\underline{\hat{P}}_j$s, between successive 24-h sampling intervals in each salinity treatment. Error bars represent the standard errors of the $\underline{\hat{P}}_j$s. A median survival time is the hour at which the survival probability curve crosses the solid horizontal line at a survival probability of 0.5.

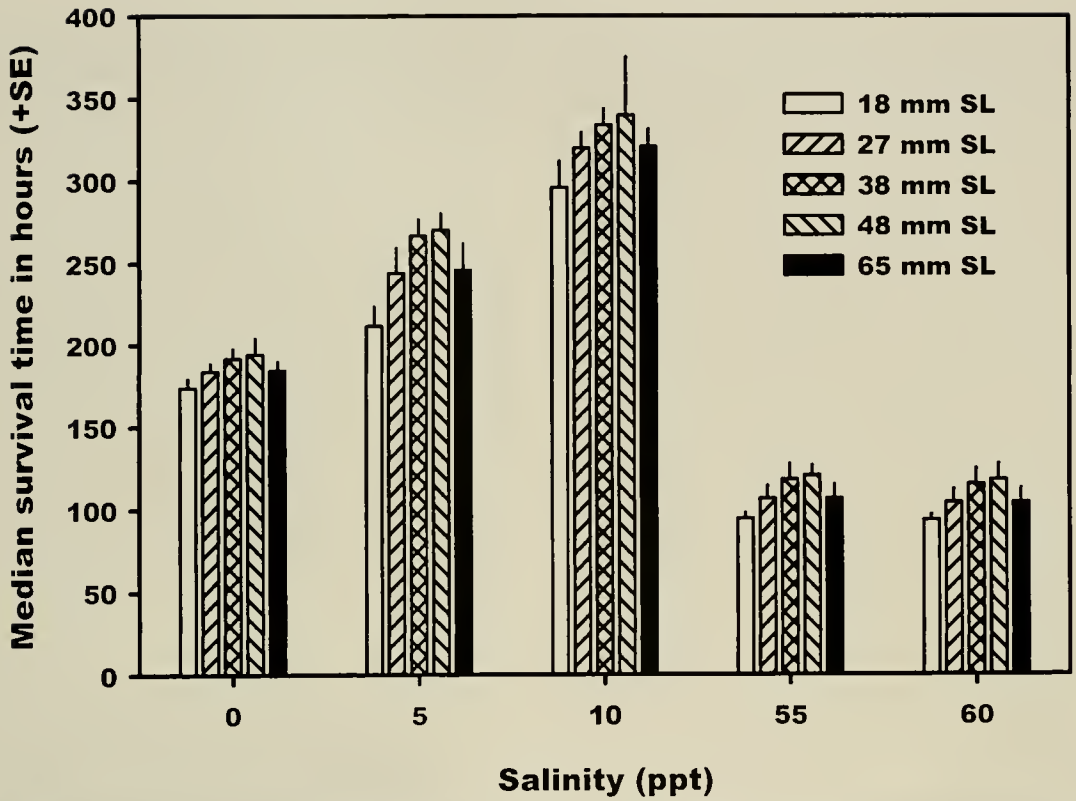

Figure 2. Median survival times (h) for Texas specimens of *Perna perna* in lethal salinity treatments adjusted to the 10th (18 mm SL), 25th (27 mm SL), 50th (38 mm SL), 75th (48 mm SL), and 90th (65 mm SL) percentile of the individual shell length (SL in mm) distribution. Error bars represent the standard errors of median survival estimates.

268 h (5 ppt), 335 h (10 ppt), 119 h (55 ppt), and 116 h (60 ppt) (Table 1).

Wald statistics for all-pairwise comparisons of lethal salinity treatment median survival times adjusted to the sample mean SL (40 mm) indicated significant treatment differences (Table 1). For the salinity treatments in which survival curves never fell below 0.5, median estimates could not be computed. However, because the odds ratio method still works, treatment survival distributions could be compared directly from their estimated treatment coefficients in the model (Eq. 3). For example, exponentiation of the coefficient for the nonlethal 15 ppt salinity treatment (Table 2), $e^{-6.002} = 0.0025$, indicates that the odds of death (in any time interval) in the 15 ppt salinity treatment were only about 0.25% ($\chi^2_{[9]} = 116.64$, $P < 0.0001$) of the odds of death in the 0 ppt salinity reference cell treatment (given SL = 40 mm). Pairwise testing of treatment coefficients indicated that the odds of death did not differ among the 15, 20, 30, 40, and 50 ppt salinity treatments whose survival probabilities never dropped below 0.5. The

odds of death did differ between the 15–50 ppt salinity level treatments and the extreme hyper- (55–60 ppt) and hyposaline (0–10 ppt) treatments. Among the lethal treatments (i.e., 0–10 ppt and 55–60 ppt concentrations), the odds of death differed between all pairs, except the 55 and 60 ppt salinity concentrations, which is reasonable, considering their survival curves were very similar (Fig. 1).

In low-salinity treatments, mussels initially responded by closing the shell valves (Fig. 3). After 72, 48, 48, and 24 h, individuals were observed to open the shell valves in the 0, 5, 10, and 15 ppt salinity treatments. At the lowest salinity treatments (i.e., 0, 5, and 10 ppt), mantle tissues were observed to swell outside of the shell valves and may actually have forced them apart. Under the extreme hypersaline conditions (e.g., 55 and 60 ppt), individuals gaped widely from the onset of treatment until death. In nonlethal salinity treatments, individuals were open normally at the first 24-h observation period. However, there seemed to be a positive correlation between the percentage of open individuals and salinity in nonlethal treatments, with fewer individuals displaying open valves at progressively lower nonlethal salinity exposures (Fig. 3). The average percentages of open individuals in the 30-day observation period and their associated salinity concentrations were as follows: 17.2 ± 7.9 SD (15 ppt), 30.2 ± 7.5 SD (20 ppt), 37.1 ± 10.2 SD (30 ppt), 36.3 ± 8.2 SD (40 ppt), and 38.7 ± 9.6 SD (50 ppt).

DISCUSSION

In this study, we used a DLFTM to estimate covariate-adjusted median survival times based on interval-level data. We believe that for interval-level survival data, our strategy of using medians (where possible) to summarize survival experience is a helpful complement to the usual survival curves and odds ratios. Unlike analysis of covariance (ANCOVA) approaches, the DLFTM, like other regression-type models, can provide meaningful estimates of median survival time at fixed covariate values even in the presence of variable interactions.

Texas *P. perna* survived and maintained normal activity (e.g., maintained byssal thread production) over salinities of 15 to 50 ppt, a salinity tolerance range similar to that of 19–44 ppt deter-

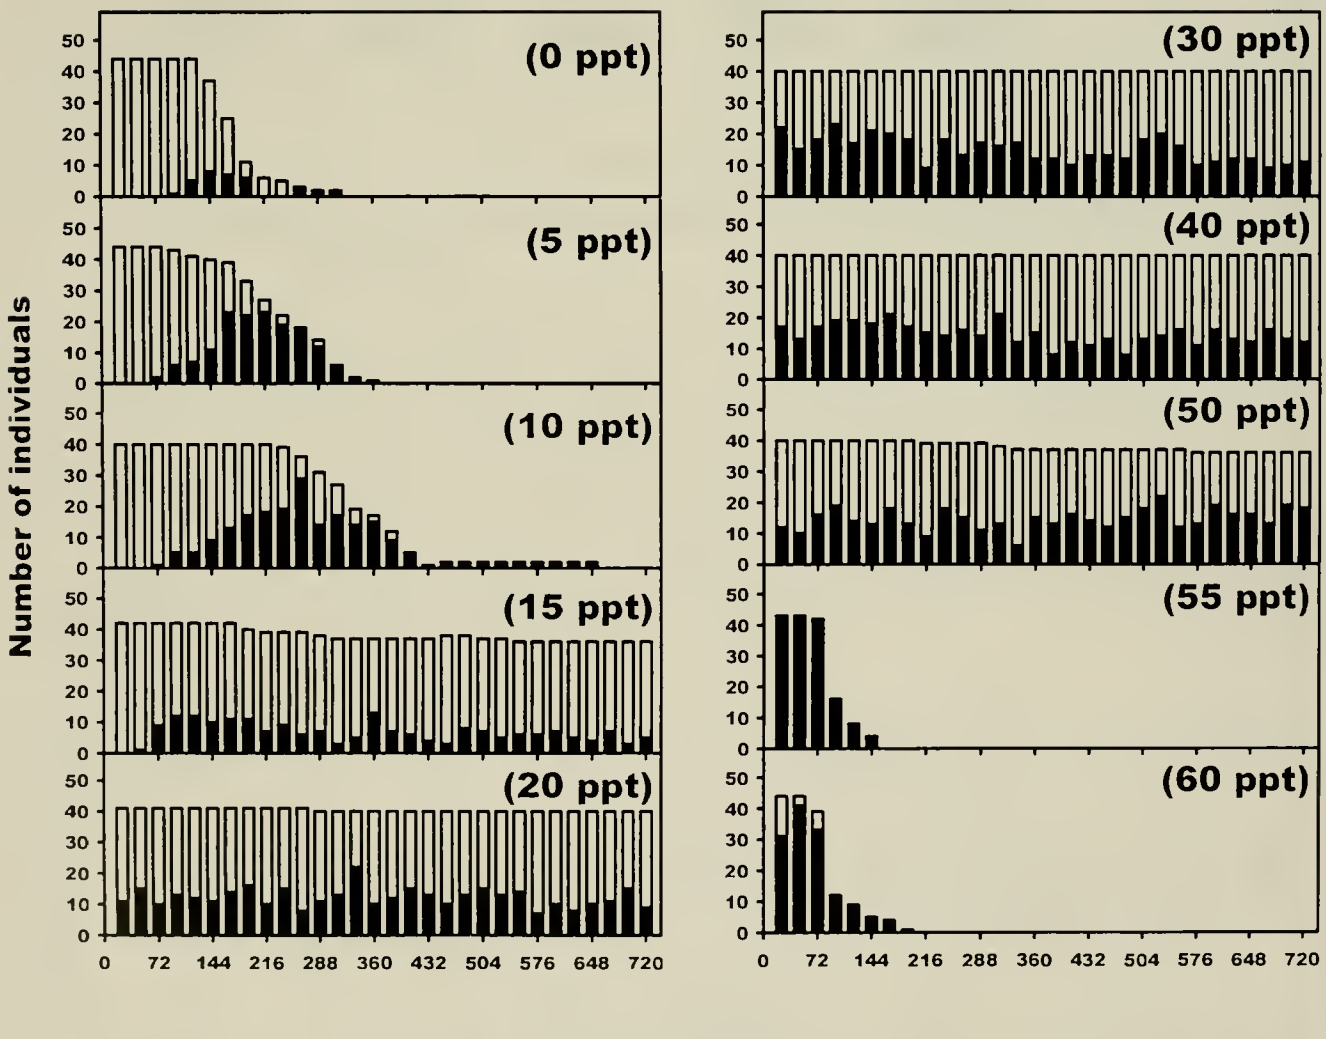

Figure 3. Shell valve closing behavior in Texas specimens of *Perna perna* exposed to chronic salinities ranging 0–60 ppt. Histogram bars represent numbers of living individuals and the solid portion of bars, the numbers of living individuals with shell valves open at each 24-h sampling interval.

mined for similar sized (45–50 mm SL) Brazilian *P. perna* (Salomão et al. 1980). A similar incipient low salinity value of 16 ppt was recorded for *Perna viridis* (L.) from India (Sundaram and Shafee 1989). Although the salinity tolerance we recorded for Texas *P. perna* generally agreed with data for South American specimens, recorded survival times were markedly different. At salinities of 4 and 9 ppt, complete sample mortality was observed after 102 hours in Brazilian specimens of *P. perna*. In contrast, Texas specimens of *P. perna* persisted for up to 360, 408, and 648 h in salinities of 0, 5, and 10 ppt, respectively. Similar to Brazilian data for *P. perna* salinity tolerance, complete sample mortality was observed to occur in individuals of *P. viridis* within 96 h upon exposure to salinities ranging 0–11 ppt (Sundaram and Shafee 1989). Median survival times reported for the Brazilian *P. perna* were 68, 49, 45, and 96 h on exposure to lethal salinities of 4, 9, 14, and 49 ppt, respectively (Salomão et al. 1980). In our study, median survival times were considerably greater than those of Brazilian specimens of *P. perna* or specimens of *P. viridis*.

Animal size was found to affect survival duration significantly in Texas specimens of *P. perna*. However, although the SL range of tested individuals was considerable (~15–70 mm SL), the range of median survival time in different sized individuals varied by only 22% or 59 h maximally. Although the largest individuals in the sample had reduced survival, the more general trend was increasing survival duration with increasing SL. This result generally agrees with that of Castagna and Chanley (1973) who demonstrated, among 29 tested marine bivalve species, that although smaller specimens generally succumbed more rapidly to lethal salinity exposures than did larger specimens, variation in individual size was not correlated with the minimum tolerated salinity.

Individuals responded to marked salinity reductions (15 ppt or ~43% dilution) by closing the shell valves. Shell valve closing behavior in bivalves allows survival of temporarily reduced salinities encountered in intertidal or estuarine environments during periods of heavy rainfall and/or freshwater run off (Gilles 1972, Davenport 1981, Akberali and Trueman 1985). Valve closure extended survival times in Brazilian specimens of *P. perna* relative to individuals with artificially propped open valves (Salomão et al. 1980). However, even when the valves are tightly closed, tissues are not completely isolated from the external environment. Thus, valve closing behavior provides protection from salinity stress only over relatively short periods. Indeed, even with the shell valves closed, *P. perna* tissues reach osmotic equilibrium within 72 h of exposure to salinities of 19–39 ppt (Salomão and Lunetta 1989). A similar value of 96 h has been reported for *Mytilus edulis* L. exposed to salinities ranging from 9–36 ppt (Gilles 1972).

The shell valve closing response is mediated by peripheral receptors located on the mantle margins and/or siphon surfaces (Davenport 1981, Berger and Kharazova 1997). These peripheral receptors are of two types: osmoreceptors, sensitive to osmotic pressure, and receptors sensitive to changes of specific ion concentrations (Berger and Kharazova 1997). Such receptors not only trigger valve closure in response to salinity change, but also enable detection of relative salinity concentrations. When transferred from full strength seawater (35 ppt) to lower salinities, the proportion of individuals of *P. perna* with closed valves was directly proportional to the seawater concentration: the lower the salinity, the greater the tendency to close the valves (Fig. 3). This result is consistent with the valve closure behavior in response to variable salinity recorded for other marine and estuarine bivalve species (Akberali 1978, Bailey et al. 1996).

Davenport (1981) found that increasing salinity is registered by special detectors located in the tentaculate portion of the inhalant siphon of *Mytilus edulis*. These receptors, requiring the presence of both sodium and magnesium ions, trigger shell valve parting at salinity concentrations similar to those that induce valve closure under declining salinity conditions (~ 17 ppt, Davenport 1981). It is unknown whether similar receptors are responsible for the gaping of individuals of *P. perna* observed in the highest salinity treatments (i.e., 55 and 60 ppt). Exposure to these elevated salinities seemed to have a narcotic effect on this species. Lack of an appropriate protective valve-closing response suggests that *P. perna* rarely encounters hyperosmotic conditions and is an indication that it is limited to marine intertidal and open-water estuarine habitats. Given that the tissues of specimens of *P. perna* will eventually come into osmotic equilibrium with their external environment, it seems that *P. perna* cannot tolerate haemolymph osmolarities of less than 430 mOsm (15 ppt) or greater than 1428 mOsm (50 ppt).

The range of salinity tolerated by marine bivalves in laboratory experiments is often a good predictor of their distribution in natural habitats (Castagna and Chanley 1973). Castagna and Chanley (1973) observed that the experimentally determined salinity tolerance of a number of marine bivalves adequately explained their distributions in nature. When a species' natural distribution did not include its entire tolerated salinity range, it was usually attributed to a species being near its geographic limit where other limiting factors, particularly temperature, became more important limiting factors. Within its endemic range, *P. perna* occurs primarily in open-water, high-energy hard-shore habitats where salinity remains relatively constant near full-strength seawater (Berry 1978). However, in Brazil, it is reported from semi-enclosed lagoons where salinities may be as low as 12.7 ppt (Marques et al. 1991). Although *P. perna* rarely occurs naturally in enclosed-estuarine habitats, it thrives when relocated to such habitats for culturing in South America and Sri Lanka (Indrasena and Wanninayake 1994). Indeed, some of the highest growth rates reported for this species are from culture grow-outs in lagoons where salinities ranged 20–45 ppt (Indrasena and Wanninayake 1994).

The salinity regimes of coastal environments vary temporally and spatially over short (tidal or storm induced) and long durations (seasonal influences). Bivalve salinity tolerance can be influenced by previous salinity experience (i.e., acclimation salinity), magnitude of salinity change, and/or rate of change (see Remane and Schlieper 1971 and Kinne 1971 for reviews). In this study, the incipient salinity limits of *P. perna* were determined by chronic exposures of up to 30 days following direct transfer from full-strength seawater (35 ppt) into one of 10 test salinities. Because of the long exposure periods involved, individuals had sufficient time to acclimate to test salinities near this species upper and lower incipient limits, allowing relatively accurate estimation of *P. perna*'s incipient salinity range. In addition, direct transfer to test salinities allowed evaluation of the colonization potential of *P. perna* after rapid, anthropomorphically mediated introduction of adults into new habitats. Pernids foul the hulls of international vessels (Carlton 1987). Thus, adult mussels byssally attached to anchor chains and/or the hulls of transoceanic vessels and barges can be transferred directly into a new habitat whose salinity regime varies from that of the source population. Our data suggest that if other environmental conditions are favorable, anthropomorphically introduced *P. perna* could colonize waters within a salinity range of 15–50 ppt.

The incipient upper and lower salinity limits determined herein indicate that *P. perna* could potentially colonize areas in the Gulf of Mexico outside of its present Texas/Mexico range (Hicks and Tunnell 1993, Hicks and Tunnell 1995). The 15–50 ppt tolerated salinity range of Texas *P. perna* suggests that this species could potentially invade most Gulf of Mexico coastal habitats, including those from which raw water is drawn by industrial and power generation facilities, particularly in the Houston ship channel and Mobile Bay; potentially making them susceptible to the macrofouling reported for this species in India (Ragapogal et al. 1995). Thus, the dispersal of this invasive nonindigenous species should continue to be closely monitored in the North American Gulf of Mexico and southern North Atlantic coastal habitats.

ACKNOWLEDGMENTS

We thank Ron Smith and Terry Riggs of Texas A&M University–Corpus Christi for collecting and shipping *P. perna* samples to Arlington, Texas. The reported research was funded by Grant NA56RG0388 from the Texas A&M Sea Grant College Program.

APPENDIX 1: EXAMPLE OF THE DELTA METHOD

The delta method is a general technique of variance propagation as follows. Let $\boldsymbol{U}$ be a p × 1 random vector that is distributed approximately multivariate normal (MVN) with mean E$\boldsymbol{U}$ and covariance matrix Var ($\boldsymbol{U}$). Let $f(z)$ be an $s \times 1$ vector function of p variables; i.e.,

$$f(z) = \begin{bmatrix} f_1(z) \\ \cdot \\ \cdot \\ \cdot \\ f_s(z) \end{bmatrix}.$$

Let J_f denote the $s \times p$ Jacobian matrix of f whose (a, b) entry is $\partial f_a/\partial z_b$. The delta method then asserts that the $s \times 1$ random vector $f(\boldsymbol{U})$ is also approximately MVN, with mean

$$E\{f(\boldsymbol{U})\} \approx f(E\boldsymbol{U}) \text{ and covariance matrix}$$

$$\text{Var}\{f(\boldsymbol{U})\} \approx J_f(E\boldsymbol{U})\{\text{Var}(U)\}\boldsymbol{J}_f^T(E\boldsymbol{U}).$$

As an illustration of the delta method in our problem, we give the details of obtaining the covariance matrix of the interval-specific estimates $\hat{\boldsymbol{p}} \equiv [\hat{p}_1(\boldsymbol{x}), \ldots, \hat{p}_k(\boldsymbol{x})]^T$ from the covariance matrix of $\hat{\theta}$ (Here $\boldsymbol{x}$ is specified and fixed). The computer program performs these calculations, as well as those for obtaining the covariance matrix of the $\hat{\underline{P}}_j$s from the $\hat{p}_j$s. Because $\hat{p}_j(\mathbf{x})$ is obtained by plugging $\hat{\theta} = (\hat{\alpha}, \hat{\beta})$ into (3), the vector $\hat{\boldsymbol{p}}$ is given by $\hat{\boldsymbol{p}} = \mathbf{f}(\hat{\theta})$, where

$$f(z) = \begin{bmatrix} f_1(z) \\ \cdot \\ \cdot \\ \cdot \\ f_k(z) \end{bmatrix}$$

and for $k \times 1$ vector $\boldsymbol{w} = (w_1, \ldots, w_k)^T$, $m \times 1$ vector $\boldsymbol{v} = (v_1, \ldots, v_m)^T$ and $\mathbf{z} = (\mathbf{w}, \boldsymbol{v})$,

$$f_j(\mathbf{z}) = (1 + e^{w_j + \mathbf{x}\boldsymbol{v}})^{-1}, \; 1 \le j \le k. \tag{12}$$

Now, because $\hat{\theta}$ is a maximum likelihood estimator, by general likelihood theory (see Serfling 1980) it holds that $\hat{\theta}$ is approximately MVN with mean $\boldsymbol{\theta} = (\boldsymbol{\alpha}, \boldsymbol{\beta})$ [i.e., the true values assumed to have generated the $\mathbf{G}_i$s via (3)] and covariance matrix (as noted above) $-\mathbf{H}^{-1}$. We applied the delta method to $\mathbf{U} = \hat{\theta}$, $E\mathbf{U} = \theta$, $\text{Var}(\mathbf{U}) = -\mathbf{H}^{-1}$, and the function $\mathbf{f}$ in (12) to get that $\hat{\boldsymbol{p}} = \mathbf{f}(\hat{\theta})$ is approximately MVN with $E(\hat{\boldsymbol{p}}) \approx \mathbf{f}(\theta) = \boldsymbol{p}(\mathbf{x}) = [p_i(\mathbf{x}), \ldots, p_k(\mathbf{x})]^T$ (the true value) and $\text{Var}(\hat{\boldsymbol{p}}) \approx \mathbf{J}_f(\hat{\theta})\{-\mathbf{H}^{-1}\}\mathbf{J}_f(\hat{\theta})$, where the $k \times (k + m)$ Jacobian $J_f(\mathbf{z})$ is given by

$$\mathbf{J}_f(\mathbf{z}) = \begin{bmatrix} \frac{\partial f_1}{\partial w_1} & \cdots & \frac{\partial f_1}{\partial w_k} & \frac{\partial f_1}{\partial v_1} & \cdots & \frac{\partial f_1}{\partial v_m} \\ \cdot & & & & & \\ \cdot & & & & & \\ \cdot & & & & & \\ \frac{\partial f_k}{\partial w_1} & \cdots & \frac{\partial f_k}{\partial w_k} & \frac{\partial f_k}{\partial v_1} & \cdots & \frac{\partial f_k}{\partial v_m} \end{bmatrix}$$

Specifically, for any $1 \le j \le k$ and $1 \le r \le k$,

$$\frac{\partial f_j}{\partial w_r} = \frac{\partial}{\partial w_r}\{(1 + e^{w_j + \mathbf{x}\boldsymbol{v}})^{-1}\} + \begin{cases} 0, & r \ne j \\ \dfrac{-e^{w_j + \mathbf{x}\boldsymbol{v}}}{(1 + e^{w_j + \mathbf{x}\boldsymbol{v}})^2}, & r = j \end{cases}$$

and for $1 \le s \le m$,

$$\frac{\partial f_j}{\partial v_s} = \frac{\partial}{\partial v_s}\{(1 + e^{w_j + x_1 v_1 + \cdots + x_m v_m})^{-1}\} = \frac{-x_s}{(1 + e^{w_j + \mathbf{x}\boldsymbol{v}})^2}.$$

APPENDIX 2: CALCULATION OF VARIANCE, VAR[$\hat{M}(\mathbf{x})$] AND COVARIANCE, COV[$\hat{M}(\mathbf{x}_1)$, $\hat{M}(\mathbf{x}_2)$] OF SL ADJUSTED MEDIAN SURVIVAL TIMES

Writing $z_j = \hat{\underline{P}}_j(\mathbf{x})$ to reduce notation, and writing $M_j(\mathbf{x}) = f_j(\mathbf{z})$, where $\mathbf{z} = (z_1, \ldots, z_k)$, $\hat{M}(\mathbf{x})$ can be written as $f(\mathbf{z})$, where

$$f(\mathbf{z}) = \sum_{j=1}^{k} f_j(\mathbf{z}) I(z_j < 0.5 \le z_{j-1}). \tag{13}$$

Now the indicator function (the source of the differentiability problem) is

$$I(z_j < 0.5 \le z_{j-1}) = I(z_{j-1} \ge 0.5)\, I(z_j < 0.5) = h(z_{j-1})[1 - h(z_j)] \tag{14}$$

where

$$h(t) = I(t \ge 0.5) = \begin{cases} 0, & t < 0.5 \\ 1, & t \ge 0.5 \end{cases}.$$

But $h(t)$ can be closely approximated (as ε approaches zero) by the function $h_\varepsilon(t) = \Phi(t - 0.5/\varepsilon)$, which is the cdf of the $N(0.5, \varepsilon^2)$ distribution (Fig. 4). In fact, $h_\varepsilon(t) \to h(t)$ as $\varepsilon \to 0$ for every $t \in [0,1] - \{0.5\}$. Furthermore, $h_\varepsilon(t)$ is, unlike $h(t)$, differentiable. Thus, we may closely approximate $I(z_j < 0.5 \le z_{j-1}) \approx h_\varepsilon(z_{j-1})[1 - h_\varepsilon(z_j)]$, and, hence, approximate $f(\mathbf{z})$ by the differentiable function $f_\varepsilon(\mathbf{z})$ for small ε:

$$f(\mathbf{z}) \approx f_\varepsilon(\mathbf{z}) \equiv \sum_{j=1}^{k} f_j(\mathbf{z}) h_\varepsilon(z_{j-1})[1 - h_\varepsilon(z_j)]. \tag{15}$$

Thus, we approximated the estimate $\hat{M}(\mathbf{x}) \equiv f(\hat{\underline{P}}_1, \ldots, \hat{\underline{P}}_k)$ by $f_\varepsilon(\hat{\underline{P}}_1, \ldots, \hat{\underline{P}}_k)$, to which the delta method applies. Details of this analysis appear in the computer code available from the authors upon request.

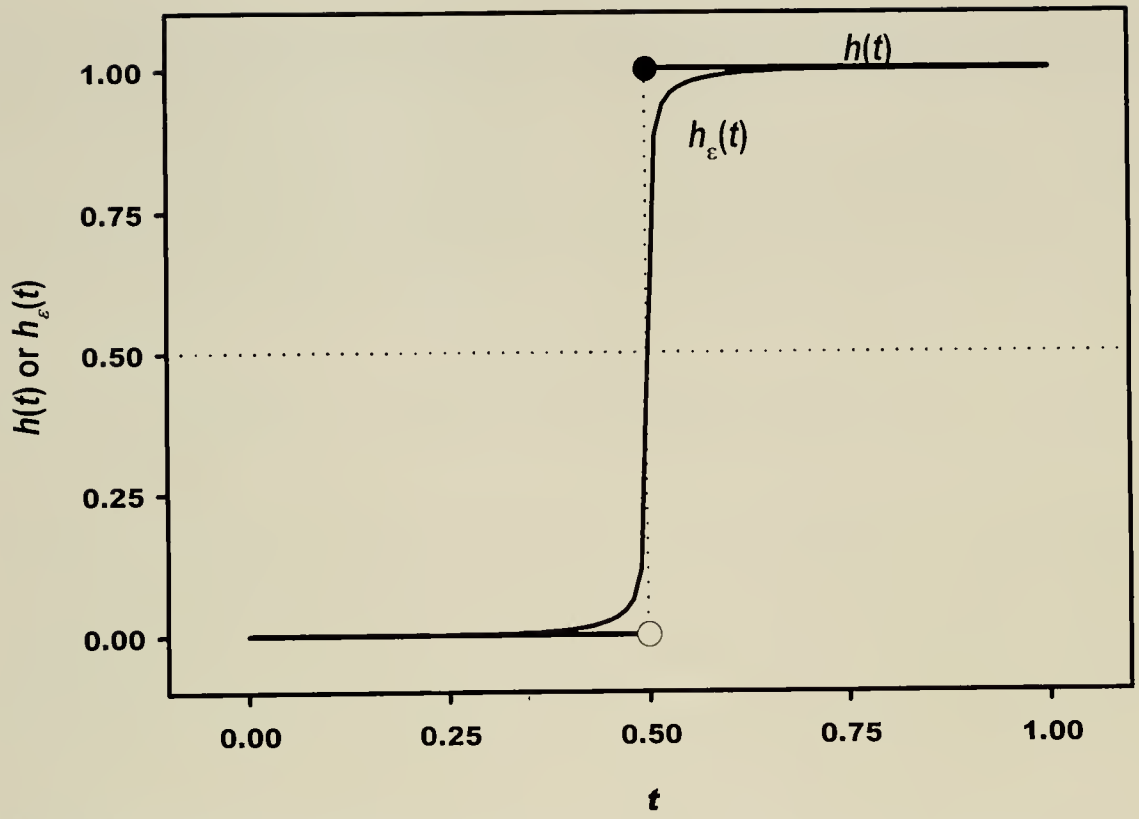

Figure 4. Illustration depicting the approximation of the indicator function $h(t)$ by the cdf of the $N(0.5, \varepsilon^2)$ distribution, $h_\varepsilon(t)$, as $\varepsilon \to 0$.

ABSTRACT The 16S rDNA from a Rickettsiales-like procaryote (RLP) infecting postesophageal tissues of black abalone *Haliotis cracherodii* Leach exhibiting signs of withering syndrome (WS) was amplified, cloned, and sequenced. The 16S rDNA sequence for the RLP was similar to that of species found in the genera *Ehrlichia, Anaplasma,* and *Wolbachia.* A polymerase chain reaction (PCR) test was developed that specifically amplifies a 160 bp segment of the 16S rDNA from the RLP associated with WS. Positive reactions were obtained for all black abalone samples of digestive gland or postesophagus known to be infected with the RLP by microscopic examinations of stained tissue sections. The PCR worked equally well for infected tissues of black and red abalone *H. rufescens* Leach. There was no amplification of genomic DNA from four other microbial species isolated from cultures of intestinal flora of abalone or from abalone deemed free of the RLP by microscopic examinations. This PCR test greatly increases the ability to detect the bacterium, because to date no means to grow the organism from marine invertebrates on synthetic media or in cell lines have been developed. This PCR test should allow detection of the RLP before the onset of clinical signs of withering syndrome in cultured or wild abalone stocks. Furthermore, the test may be useful in identifying reservoirs or other related RLPs in other marine invertebrates.

KEY WORDS: Polymerase chain reaction, ribosomal DNA, Rickettsiales, abalone, *Ehrlichia, Haliotis*

INTRODUCTION

The black abalone *Haliotis cracherodii* Leach, a species once common along much of the intertidal zone of southern California's rocky beaches, has suffered severe negative impacts because of the disease termed withering syndrome (WS) (Alstatt et al. 1996., Friedman et al., 1997, Haaker et al. 1992, Tissot et al. 1991, VanBlaricom et al., 1993, 1996). Affected populations of black abalone have been reduced to 1–10% of population densities observed before the onset of WS (Haaker et al. 1992). The disease has now been observed among farmed red abalone (*H. rufescens*) (Moore et al. in press), and this has prompted the California Department of Fish and Game to place a partial ban on movement of cultured red abalone from locations where WS is endemic to locations free of this disease. The epizootic manner in which the disease has spread throughout black abalone in the Channel Islands and the mainland indicate a role for an infectious etiologic agent (Lafferty and Kuris 1993). Although not completely proved, evidence suggests that WS is caused by a previously undescribed Rickettsiales-like prokaryote (RLP), which infects gastrointestinal epithelia (Friedman et al. 1997, Gardner et al. 1995). Withering syndrome and the associated RLP have also been documented in wild and cultured red abalone, *Haliotis rufescens* Leach, (Haaker et al. 1992, Moore et al. in press). Because of the inability to culture most marine RLPs, differentiation of these organisms is difficult and is based upon morphological characteristics using light and electron microscopy. Sensitive and accurate detection of the WS-associated RLP is critical to our understanding and control of the spread of WS. The goal of the current study was to develop a polymerase chain reaction (PCR) test to improve our detection and understanding of the biology of the RLP causing WS in abalone and other as yet unidentified hosts.

MATERIALS AND METHODS

DNA Extractions, Sequencing, and Alignments of rDNA

DNA isolation from whole tissue and from bacterial cells was performed as described by Sambrook et al. (1989) and Friedman et al. (in press). Briefly, rinsed tissues were homogenized in lysis/proteinase K buffer. After 1 h at 55 °C, the DNA was extracted in a phenol-chloroform solution. Isoamyl alcohol was added, mixed for 10 min, and centrifuged. The top aqueous phase was removed and 1/10 volume of 3 M sodium acetate was added. Cold absolute ethanol was added to precipitate the DNA. The pellet was washed in 70 % ethanol, air-dried, and resuspended in Tris-EDTA (TE) buffer. Alternatively, DNA was prepared using the QIAmp Tissue Kit (Qiagen Inc., Valencia, CA) following the manufacturers "mouse tail protocol". Bacterial 16S rDNA from infected abalone tissue was amplified using EUB A and EUB B universal eubacterial 16S rDNA primers (Giovannoni 1991). The RLP 16S rDNA gene was cloned into pCR2.1 using a TOPO Cloning Kit (Invitrogen, San Diego, CA) following manufacturer's protocols. Clones were screened using PCR with primers that flanked the multicloning site of the vector. Positive clones were selected from among those that had an insert of the appropriate size (~1550 bp). The 16S rDNA sequencing and alignments of sequences were performed as described previously (Andree et al. 1997). The completed sequence was used in a BLAST search of GenBank to confirm the similarity of the sequence to other Rickettsiales. The species appearing in the results of the BLAST search were compared with other closely related bacterial species in a pairwise analysis of sequence similarity (Table 1) in addition to a phylogenetic distance analysis (Friedman et al. in press).

Primer Selection and Oligonucleotide Synthesis

A BLAST search of GenBank indicated three species, *Anaplasma marginales, Ehrlichia bovis*, and *Wolbachia pipientis*, were most similar to the 16S rDNA sequence amplified from infected abalone (clone designation p16RK3; GenBank accession number: AF133090). The four sequences above and that of *Piscirickettsia salmonis* and a Rickettsiales-like prokaryote from shrimp (Frelier et al. 1993) were aligned to identify those sequences most unique to the RLP from infected abalone. Several primers were selected for synthesis and testing. In an initial trial, two primers designated RA5-1 [$^{5'}$GTTGAACGTGCCTTCAGTTTAC$^{3'}$] and RA3-1 [$^{5'}$CTGAGGCCATCTGTTAAAATGG$^{3'}$], were synthesized (Gibco BRL, Inc., Gaithersburg, MD) and used in an initial screening of samples containing enriched RLP from abalone tissues. The best results were obtained using these primers in conjunction with an annealing temperature of 55 °C. An amplified product of 946 bp was obtained from all RLP-enriched samples tested (data not shown). Subsequent tests with DNA samples extracted from digestive gland tissues of diseased animals showed a poor correlation with the histology results (e.g., samples from known positive abalone were negative by PCR). We speculated that the 16S rDNA of the normal gut flora could be hybridizing with the primers for the PCR, reducing efficiency of amplification. Accordingly, we designed new primers for the WS-PCR based on a second alignment using the 16S rDNA sequences from p16RK3, *E. bovis, A. marginales, W. pipientis, P. salmonis*, and *E. coli* as a representative of intestinal flora. This alignment showed the sequence of primer RA3-1 to be completely conserved in the 16S rDNA of *E. coli*, and this could have been contributing to the poor results observed in the PCR by nonspecific hybridization of this primer to bacterial DNA in the sample. We, therefore, designed three additional primers designated RA5-6 [$^{5'}$GAAGCAATATTGTGAGATAAAGCA$^{3'}$], RA3-6 [$^{5'}$ACTTGGACTCATTCAAAAGCGGA$^{3'}$], RA3-8 [$^{5'}$CCACTGTGAGTGGTTATCTCCTG$^{3'}$] for testing as potential primers for the WS-PCR. The primers RA5-1 and RA3-6 were designed to amplify a sequence of ~160 bp from the 5′ end of the 16S rDNA (Fig. 1). The primer pair RA5-6 and RA3-8 was designed to amplify a sequence of ~230 bp from the 3′ end of the 16S rDNA (Fig. 1). The previously extracted DNA samples were then retested with these new primer sets.

We also examined the possibility of using crude cell lysates rather than purified DNA in the assays for the WS-PCR. Tissue samples from 26 abalone were prepared by homogenization in TE buffer and boiling for 5 minutes at 100 °C. From this solution, 3 µl was added to a PCR cocktail. After amplification, DNA was separated on 1.5 % agarose gels.

PCR Amplification of rDNA

All amplifications were performed in standard 50 µl reactions containing 10 mM Tris-HCl pH 8.3 (at 25 °C), 50 mM KCl, 1.5 mM $MgCl_2$, 0.001 % w/v gelatin, 400 µM dNTPs, 5 µM tetramethyl ammonium chloride, 40 pmoles of each primer, and 2 U Taq polymerase. The PCR thermal cycler used was a model PTC-200 (MJ Research, Watertown, MA).

A 160 bp fragment (using primers RA5-1 and RA3-6) of the 16S rDNA from the RLP was amplified using 40 cycles of 1 min at 95 °C, followed by 30 sec at 50 °C, followed by 30 sec at 72 °C. The amplification cycles were preceded by a denaturation step, where samples were held at 95 °C for 5 min and followed by an extended elongation step where samples were held at 72 °C for 10 min.

Specificity of the PCR

Adult black abalone were collected from the Vandenberg Air Force Base, CA (in July 1996) where WS is epidemic and from Monterey, CA (in December 1998) where the RLP has been recently detected but where no signs of clinical WS have yet become apparent (Finley and Friedman, unpubl. obs). Additional samples of adult abalone were collected from the following two locations where neither WS nor the RLP had been observed: black abalone from Carmel Point in August 1997 and red abalone from Shelter Cove in December 1998. Farmed red abalone obtained in January 1999 from a facility in Central California were also examined. Visual assessment of WS was determined according to Friedman et al. (1997). Digestive gland, postesophagus and/or epipodium were collected and stored at −80 °C until DNA extraction. The hemolymph of abalone contains no blood-clotting factor; there-

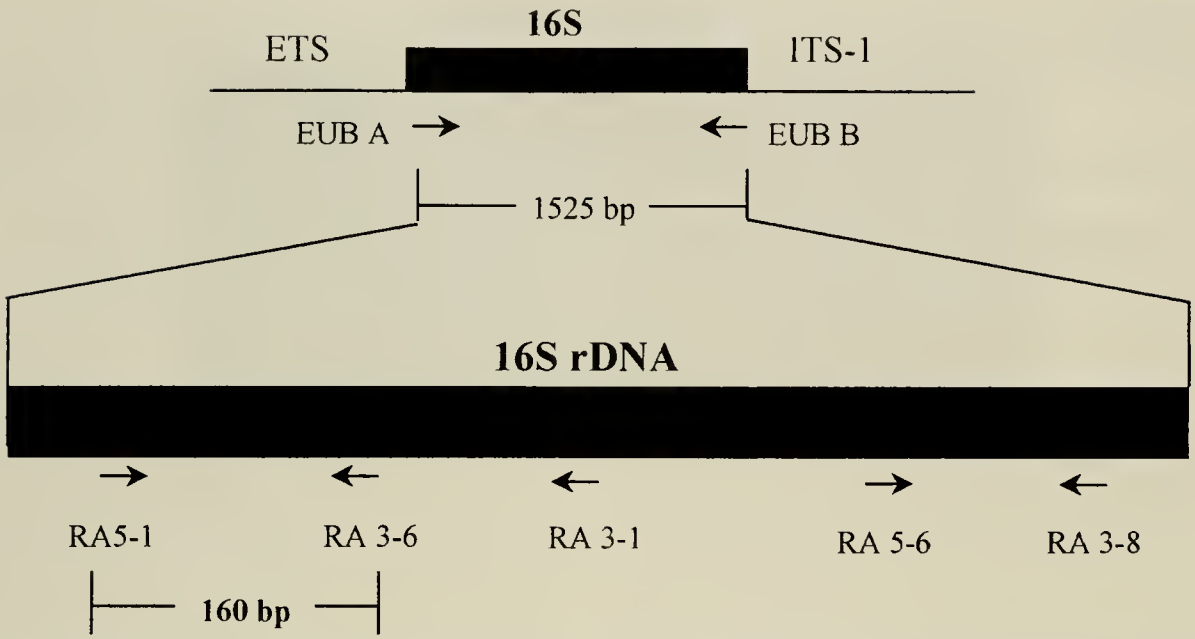

Figure. 1. Diagrammatic representation of the approximate location and orientation of primers used for development of the PCR assay to detect the Rickettsial-like prokaryote among abalone with withering syndrome (WS). Primers EUB A and EUB B were used in the initial amplification of the 16S rDNA from infected tissues.

fore, collection of samples from internal organs is fatal for the animal. DNA samples obtained from different abalone tissues were tested to identify those best for use in PCR assays and to determine if the RLP could be detected in nonlethal samples of the epipodium.

Genomic DNA of endogenous gut flora was tested for possible nonspecific amplification of DNA using the WS diagnostic primers. To obtain cultures for DNA extraction, postesophagus tissue (0.8–2.0gm) was dissected from three black abalone (Vandenberg Air Force Base, CA) and held separately in sterile vials containing 10 mL of 0.2 μm-filtered seawater, on ice. Vials were shaken vigorously to dislodge and suspend bacterial flora associated with epithelial surfaces, and the tissue was removed from each vial. The bacterial suspensions were spread onto marine and TCBS agar plates that were held at 15 °C. Colonies appearing after 7 days were streaked on marine agar plates. Four colonies from the TCBS plates and two from the marine agar plates were selected and passed several times on marine agar. Based on biochemical (API NFT Biomerieux Vitek, Hazelwood, MO) tests, supplemental tests, and colony morphology on TCBS and marine agar, four distinct isolates were obtained (Table 2). Cultures grown in TSB broth (supplemented with 2 % additional NaCl) were centrifuged (3,200 *g*, 10 min, 4 °C), resuspended in TE buffer (10 mM Tris-HCl, pH 7.5, 0.1 mM EDTA), and frozen at −80 °C. The presence of any RLPs among the colonies tested was precluded by the multiple passages of the isolates on artificial media. DNA was extracted from the bacterial cultures, as described above. Approximately 150 ng of genomic DNA from each of these isolates was tested with the primers RA5-1 and RA3-6.

Histology

Several 3-mm cross sections that included mantle, epipodium, postesophagus, digestive gland, and foot muscle were excised from each abalone, placed in Invertebrate Davidson's solution (Shaw and Battle 1957) for 24 h and processed for routine paraffin histology. Deparaffinized 5 μm tissue sections were stained with Harris's hematoxylin and eosin (Luna 1968) and assessed for the presence of RLPs, and condition of the foot muscle and digestive gland were evaluated (Friedman et al. 1997). The digestive gland was scored as 0 if normal, with terminal acini occupying most of the tissue present. A score of 1 represented a moderate degeneration of or replacement of terminal acini with transport ducts or connective tissues: whereas, a score of 2 represented a severe loss of acini. Similarly, condition of the foot muscle was scored as 0 when muscle bundles were tightly packed, 1 when a moderate loss

TABLE 2.

Characteristics of four postesophagous bacterial isolates grown in culture and tested for reactivity using the WS-RLP PCR protocol.

Isolate	Gram	Shape	Sucrose Reaction on TCBS	O/129 Sensitivity	H2S Production	PCR Reaction
150-A	Negative	Rods	Positive	Sensitive	Negative	Negative
150-B	Negative	Rods	Negative	Sensitive	Negative	Negative
213	Negative	Rods	Negative	Resistant	Positive	Negative
239	Negative	Rods	Negative	Resistant	Negative	Negative

of muscle bundles and concomitant increase in connective tissue was observed, and 2 when such loss was severe.

RESULTS

PCR Detection of the Putative Etiologic Agent of Withering Syndrome

The DNA from tissues of abalone with naturally acquired infections was screened for the presence of RLP DNA. Tissues from abalone collected from geographic regions where signs of WS and the associated RLP were absent served as negative controls. In addition, epipodial tissue was tested to determine if nonlethal samples could serve as diagnostic material for PCR analysis.

In total, we examined 23 animals by PCR (Table 3). We compared epipodium, digestive gland, and/or postesophagus for some individual animals. The 160 bp amplicon was present only in tissues from those animals that came from WS enzootic areas (most of which had proved to be positive by microscopic examination). The identity of the amplified DNA was confirmed by automated sequencing (data not shown). In addition, the identity of the species being detected was confirmed by *in situ* hybridization experiments in which the PCR primers were used as probes (Antonio et. al. in press). The yield of amplified DNA was greatest from postesophageal tissue (Fig. 2). This agrees with microscopic observations that demonstrated the postesophagus was more highly infected than the digestive gland. A weak amplification of DNA was obtained from some samples of epipodium from a subset of animals that tested strongly positive using the digestive gland.

Specificity of the PCR

Of the primer pairs tested, RA5-1 and RA3-6 gave the best results at an annealing temperature of 50 °C. Retesting of samples with this new primer produced a 160 bp amplicon from all tissues known to be positive for the RLP by microscopic examinations. In addition, all samples considered free of the RLP by microscopic examination were negative by PCR. There was no amplification of genomic DNA from the selected bacterial isolates from the intestine of black abalone or from a recently isolated *Piscirickettsia*-like organism isolated from white sea bass *Atractoscion nobilis* Ayres in California (unpubl. obs.). Only DNA extracted from abalone tissues known to contain RLP yielded a 160 bp amplicon. All samples of postesophagus and digestive gland from RLP-infected red and black abalone tested positive. There was a 250 bp amplicon present from the epipodial tissue of six black abalone collected from Vandenberg, Monterey, and Shelter Cove. However, two of these six samples yielded both amplicons (160 bp and 250 bp). Those with only the 250 bp amplicon were scored as negative based on the difference in the molecular weight and sequencing of the larger amplicon that indicated it was not related to bacterial 16S rDNA.

DISCUSSION

Diagnosis of infectious disease during the past century has generally relied on such methods as culture, direct observation of parasites or, more recently, antigen-based assays (Sethi et al. 1996). These methods may involve expense and time for sample

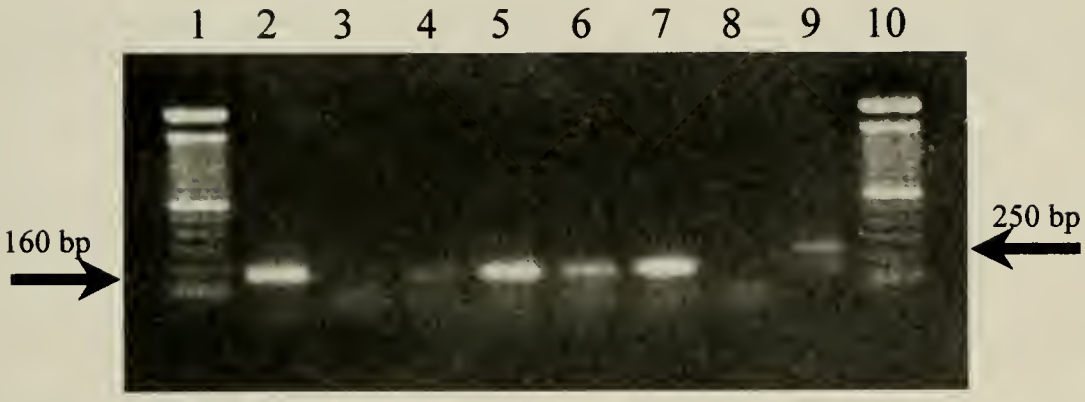

Figure. 2. Detection of a Rickettsial-like prokaryote in tissues from abalone with withering syndrome (WS) using a newly developed PCR assay. Approximately 300 ng of genomic DNA was used for each sample assay. Lanes 1and 10: 100 bp ladder molecular weight standard; lane 2: positive control sample (10 ng of plasmid p16RK3 containing cloned 16S rDNA); lane 3: negative control sample (uninfected black abalone postesophagus tissue); lanes 4 and 5, respectively: digestive gland and postesophagus of infected black abalone; lanes 6 and 7, respectively: digestive gland and postesophagus of infected red abalone; lane 8: negative control sample (150 ng of genomic DNA from prokaryote cultured from the gut of abalone); lane 9: epipodial tissue from infected black abalone displaying the 250 bp amplicon.

preparation or may lack sensitivity in detecting low numbers of parasites. Furthermore, many parasites, including the RLP from abalone, have not been cultured outside the host animal (Arnoldi et al. 1992, Mari et al. 1995, Sethi et al. 1996). Molecular approaches to parasite detection such as the PCR are rapid, reproducible, and relatively easy to conduct (Andree et al. 1998, Mauel et al. 1996, Sethi et al. 1996). Early and accurate detection of parasites in marine invertebrates is critical, because therapeutic approaches are limited, and avoidance becomes a principal means of disease management and resource protection.

Withering syndrome is a fatal, infectious, bacterial disease of both wild and cultured abalone in California (Friedman et al. 1997). Diagnosis of WS, like many diseases, currently relies on observation of gross signs of affected abalone and detection of the RLP in target tissues by microscopic examination of stained tissue sections. Unfortunately, inclusions of other intracellular bacteria are frequently found in shellfish and are often morphologically indistinguishable from the RLP associated with WS (Friedman and Hedrick, unpubl. obs.). We have confirmed the PCR test differentiates among RLPs in abalone tissues by *in situ* hybridization experiments that utilize the PCR primers as probes (Antonio et al. in press). The probes only hybridize to the RLPs that correlate with the observation of disease symptoms (data not shown). The RLP is, therefore, more easily and rapidly detected by the application of such DNA diagnostic tests as PCR than by microscopy.

This PCR test should prove to be a useful tool for the study of WS, especially for epidemiological investigations of the modes of transmission and reservoirs for the parasite in the marine habitat. In addition, experimental exposure studies combined with this PCR assay should help to identify naturally resistant populations of black abalone. The PCR assay provides direct visualization of specific bands on ethidium bromide stained gels, more rapid diagnosis than microscopic examination of tissue sections, and obviates the need for cell culture isolation of the parasite. Furthermore, we presume the PCR test will detect organisms at lower levels of infection than microscopic examination of stained tissue sections.

The primers designed for PCR detection of the RLP were chosen after alignments showed sequences obtained from *Anaplasma marginales, Ehrlichia bovis, Wolbachia pipientis, Piscirickettsia salmonis, Escherichia coli*, and an unnamed Rickettsia-like bacterium from shrimp found no homologous sites for hybridization. The lack of hydridization of the RLP primers with genomic DNA isolated from bacterial flora cultured from the postesophagus of abalone and from *P. salmonis* genomic DNA from cells grown in tissue culture was indicated by the absence of any amplified products following the PCR. The assay performed equally well on RLP-infected black and red abalone. There was some nonspecific amplification from epipodial tissues of a small number of the black abalone tested but the product (250 bp) was clearly different in molecular weight and sequence from the expected 160 bp amplicon. This 250 bp product may be the result of surface contamination of the epipodium, because it was not observed in red abalone, or black abalone from all locations.

Some heavily infected animals gave positive test results with epipodial tissues; however, in general, most samples of the epipodium were negative by PCR. The relatively weak positives among the epipodium samples may represent cross contamination (with more heavily infected tissues) during sampling or the adherence of RLPs on the epipodium as shed from infected animals in crowded tanks during transport or holding before sample collection. This concern combined with the appearance of the 250 bp amplicon in nonlethal epipodial biopsies discourages us from recommending this sampling approach for detection of the RLP. A more reliable approach is to collect postesophagus or digestive gland tissues from each animal, which requires sacrificing the animal (as do current microscopic procedures).

As mentioned above, an additional application of the PCR primers is their use for *in situ* hybridization (ISH) to visualize the parasite in various tissues or alternate hosts and to differentiate this bacterium from other RLPs commonly observed in marine species (Elston 1986, LeGall et al. 1988). Future work utilizing ISH may also identify portals of entry and early developmental forms not easily seen by standard microscopic examinations, as shown with other parasites of aquatic hosts (Antonio et al. 1999; Antonio et al. in press).

ABSTRACT The microstructure, deposition of rings, and growth checks in the pinto abalone, *Haliotis kamtschatkana* Jonas, were examined at seven sites in southeast Alaska. Rings were of calcium carbonate with prismatic or block-like structure or were of organic material (called brown rings); sometimes both types were juxtaposed in a compound ring. Rings alternated with nacreous layers having a brick-like or laminar structure. Laminar thickness was correlated with ambient sea temperatures and provided internal evidence of periodicity of ring deposition. One ring a year appears to be deposited in the spire of this abalone in about mid-summer, and a growth check is laid down at the growing edge of the shell in about mid-winter. Rates of deposition of the rings and growth checks were validated by comparison with known growth rates from mark-recapture experiments at one site, and modal analysis of length frequency data at others. Examination of a sample of shells of known age confirmed a deposition rate of one ring a year. Brown rings appear to be laid down adventitiously and were excluded from ring counts for aging purposes. The three independent techniques, rings, growth checks, and modal analysis, gave consistent juvenile growth rates at 7 sites of 14–18 mm/y during the first 4 y. Thereafter, growth rates followed a declining exponential curve. Growth rates differed little between sites, and mean parameters of fitted von Bertalanffy growth parameters for seven sites were: $K = 0.20$; $L_\infty = 125.9$ mm.

KEY WORDS: Chronology, growth rings, growth checks, shell-aging, growth rates, abalone, *Haliotis kamtschatkana*

INTRODUCTION

The molluscan shell is known to cryptically encode, within its microstructure, information on seasonal growth, age, and even habitat relations (Bandel 1990). Knowledge of the microstructure of the abalone shell is accumulating. It is known that the abalone shell deposits prismatic rings in the spire that are useful for aging, and that the shell's aragonitic laminae reflect seasonal temperature changes that confirm the periodicity of ring deposition (Shepherd et al. 1995, Shepherd and Avalos-Borja 1997).

The pinto (or northern) abalone, *Haliotis kamtschatkana*, so named because of its striking color pattern on the epipodium, occurs from southeast Alaska to northern California and was the basis of small commercial fisheries in British Columbia and Alaska until declining stocks caused their respective closures in 1990 (Farlinger and Campbell 1992) and 1995 (Woodby et al. in press). However, recreational and subsistence harvest of the pinto abalone continues in Alaska, and an understanding of the species' population dynamics, growth rate specifically, is necessary for the management of the existing stocks and the rehabilitation of those that have declined.

In this paper, we first describe structural features of the pinto abalone shell. This shell lays down nonpigmented, and occasionally pigmented, rings in the spire, which are clearly visible in horizontal shell sections, and periodic growth checks at the shell's growing edge. We interpret microstructural and ultrastructural properties of the shell to show the periodicity of ring deposition in the shell. We obtained samples of shells from wild populations and estimated the rates of deposition of the rings with size, and the sizes at which checks were laid down. Then we used shells of known age and independently obtained field data on the growth rate to confirm the rate of deposition of the rings and checks. We show that rings are laid down in summer and checks in winter and apply the techniques to estimate the growth rate of this abalone at a number of sites in southeast Alaska.

MATERIALS AND METHODS

Data Collection

Shell samples of the pinto abalone were collected by diving from seven sites in southeast Alaska (Fig. 1). At each site, divers searched intensively from the shallow sublittoral to the lower depth limit of the abalone at a depth of 10–15 m and specifically under boulders for all abalone in the size range 0–100 mm shell length (SL), and at some sites above 100 mm as well. We also collected the dead shells of abalone encountered.

Using the method of Shepherd et al. (1995), we took horizontal sections of each shell by grinding the spire with a disk grinder until a minute hole appeared in the shell, then polishing the section with sequentially finer abrasive (500–1,200 grit), and finally etching the surface with dilute HCl. The horizontal section reveals a series of concentric prismatic layers (called rings), laid down alternately with aragonitic nacre. The number of rings in each section was counted under a low-power binocular microscope. The prismatic layers are opaque and sometimes faintly honey-colored. Examination of the section showed clearly whether the most recently laid material was nacreous or prismatic. A few shells (2% of the total), bored around the spire by boring bivalves or annelids, were unreadable and were discarded.

Vertical sections of a subsample also were cut across the midpoint on the spire with a slow-speed electric saw with a diamond disc, were polished and were etched as described above, and then were cleaned in an ultrasonic bath for further analysis.

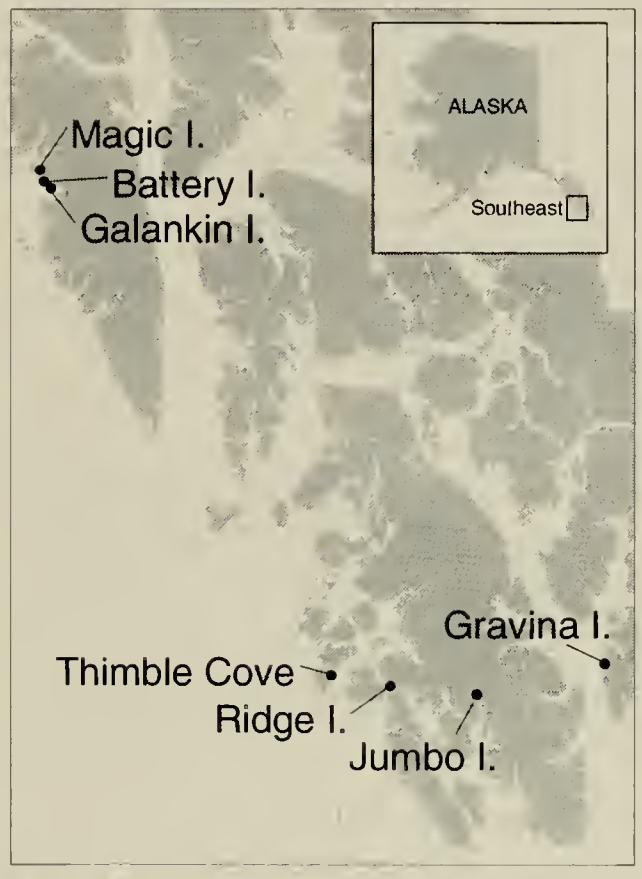

Figure. 1. Map of southeast Alaska showing sampling sites. Locations: Magic Island, 57°05′45″/135°24′07″; Battery Island, 57°03′26″/135°22′55″; Galankin Island, 57°02′04″/135°20′05″; Thimble Cove, 55°18′46″/133°34′42″; Ridge Island, 55°16′26″/133°12′18″; Jumbo Island, 55°14′37″/132°39′55″; and Gravina Island, 55°21′13″/131°51′23″.

To examine the variation in crystalline ultrastructure across the inner nacreous layer of vertical sections, we made a transect from the outer to inner shell surface at right angles to the prismatic layers and a series of micrographs (×5,000) were taken under a scanning electron microscope (SEM) (JSM5300, JEOL). The thickness of aragonitic laminae was measured at two sites on each micrograph with three replicate measurements per site. Each measurement was of 10 adjacent laminae from which a mean laminar width was calculated for each site. We chose a transect location on the vertical section where the rings were evenly spaced and took 3–5 micrographs at about equal intervals between each ring. The main elemental composition of rings was examined by X-ray microanalysis with energy-dispersive spectroscopy. In all, nine vertical sections were examined in detail with SEM.

We compared seasonal variation in sea surface temperatures with laminar widths to elucidate the periodicity of ring deposition. Monthly mean temperatures were derived from optimally interpolated weekly surface observations and satellite measurements at 1° resolution (Reynolds and Smith 1994). The data set was provided by the National Center for Atmospheric Research and was developed at the National Center for Environmental Prediction of the National Oceanic and Atmospheric Administration.

Pinto abalone, presumptively 0–4 y old, lay down growth checks (described in Results), which are best seen with transmitted light (Fig. 7) in shells to about 70–80 mm SL. Larger shells appear also to lay down growth checks in the shell, which may be seen by incident light; however, they are not clear, and their interpretation was difficult and outside the scope of this study.

We measured SL to the 1st, 2nd, 3rd, and 4th growth checks (SL_1, SL_2, SL_3, and SL_4, respectively) where these checks were visible for shells from four sites with sufficient data. Occasionally, a double check or another secondary, less conspicuous check was observed between these checks. In the former case, length to the checks was averaged, and in the latter case where we were uncertain as to which was the primary check, we measured the SL to the former of the two. In order to estimate when the growth checks were laid down, we first estimated for each site (except for Battery Island and Jumbo Island, for which there were insufficient data) the mean length at a presumed age of 1 y. These lengths were extracted from Table 1 for three sites and from the mean length of shells with one ring at Galankin Island. We then estimated the mean proportion of the annual growth achieved before deposition of the first growth check. By assuming that the growth checks were laid down exactly 1 y apart, and that the site-specific growth rates were those calculated in Table 2, we calculated the proportion of the 2nd, 3rd, and 4th year's growth achieved before deposition of the respective growth check for that year.

We examined seven shells of known age. These abalone were taken from the wild at Sitka at a size of about 50 mm SL in the summer of 1978 and were maintained in aquaria at Seward. The shells were estimated from growth checks to have been about 3 y old at capture and were assigned a birth date of July 1, 1975. The abalone died between 1985 and 1994, and the year of death was recorded on the shell. We assumed that each abalone died on July 1 of the year marked on the shell. In addition, there were two shells marked at 82 and 92 mm SL, respectively, and at liberty off Dempster Island in British Columbia for 5 y. We estimated the number of rings present at the date of tagging, from length, in the light of the known growth rate for that site, and by deduction from the number present at the date of capture, and the estimated number of rings deposited during the period between dates of tagging and recapture. Growth checks in the shells were counted, and the presence of checks at lengths near those recorded for SL_1–SL_4 in Table 2 was inferred where not visible.

Statistics

We estimated the growth rate by two methods, both independent of interpretation of ring counts and growth checks. First, where there were adequate length frequency data, we used the EMMIX program to separate modes. The procedure fits Gaussian curves and uses maximum likelihood methods to separate them (MacLachlan and Peel 1998, MacLachlan et al. 1999). The modes were assumed to be annual year classes because the pinto abalone has a narrow summer spawning season (reviewed by Sloan and Breen 1988). Modes are conspicuous for at least the first 4 y, but less so after that. We followed Fournier and Breen (1983) and Breen and Fournier (1984) and considered that the first mode at 15–25 mm SL appearing in summer samples was the 1-y-old cohort and that each succeeding mode was 1 y older. We estimated growth rates from modal intervals at several sites. Second, we examined a subset of mark-recapture data from Gravina Island where the period between dates of tagging and recapture was about a year (Woodby et al. in press) and derived mean juvenile growth rates for that site.

In the regressions of length versus number of rings, there is an unknown measurement error in the count of rings, suggesting that

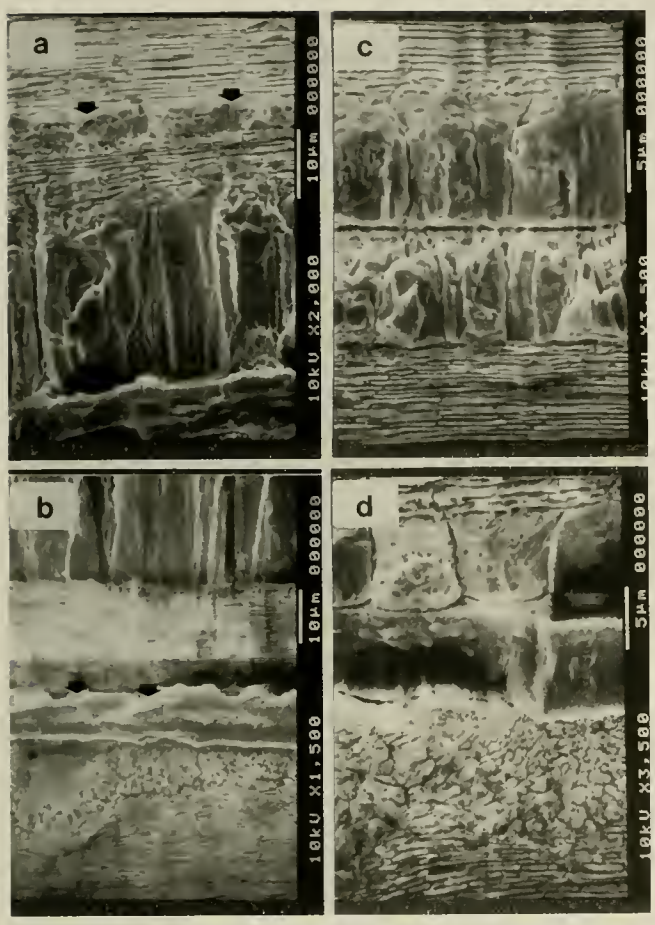

Figure. 2. Types of rings in *H. kamtschatkana*. The deposition of shell, and the descriptions below, go from top to bottom in each micrograph. a) Successive layers of nacreous laminae, a minor ring (arrows), more laminae, and the first major ring of block-like prismatic structure. b) Successively, a major ring, nacreous laminae, and a brown ring of organic material (arrow) followed by irregular material and lastly nacreous laminae. c) Nacreous laminae, followed by a double ring, and then more laminae. d) A compound ring comprising block-like prisms followed sequentially by an organic brown ring, irregular material and, last, nacreous laminae.

the regression should be formulated as an "error-in-variables" model (Model II, see Ricker 1973). However, the regressor variable is not normally distributed, hence the methods of solution are complex (Fuller 1987). Acknowledging this problem, and assuming that the measurement error is small, we note that the slopes (growth rates) at each ring interval may be slightly biased toward zero when formulated as a standard linear regression.

On the assumption that rings were laid down annually, von Bertalanffy growth parameters and standard errors were estimated with a Gauss-Newton nonlinear regression (SAS 1996).

RESULTS

Microstructure

The rings of *H. kamtschatkana* show variation in microstructure. The initial minor ring seen in a proportion of shells under optical microscopy was usually separate from but occasionally juxtaposed to the first major ring overall or to part of its length in the section (Fig. 2a), so that it may not be distinguishable from the major ring at low magnification. SEM microscopy revealed that

TABLE 1.

Regression equations of SL versus presumptive age in years (A) for data on modal means of length-frequency distributions and presumptive age.[a]

Site	Regression Equation (SE)	R^2	Length at Age 1 y (mm)
Gravina Island	SL = 17.0 + 11.0 (0.8) A	0.99	[b]
Magic Island	SL = −3.4 + 18.5 (1.3) A	0.99	16.3
Thimble Cove	SL = 7.9 + 13.8 (0.2) A	1.00	21.5
Ridge Island	SL = 12.2 + 13.1 (0.8) A	1.00	22.3

[a] The age at one year is the modal mean of the initial mode in the length-frequency distributions.
[b] No 1-y-old animals were found.

rings were of two kinds. Most were of calcium carbonate, were unpigmented, were of simple, prismatic, or block-like structure with very little organic material (Fig. 2a, c), and were presumed to be composed of aragonite and/or calcite, as is found in other abalone species (Dauphin et al. 1989, Hawkes et al. 1996). The second type of ring contained relatively little calcium but was high in carbon, sulphur, oxygen, silicon, and sodium, indicating a likely organic composition (Fig. 2b, d); these rings were pigmented when viewed under the optical microscope and are termed brown rings. The brown rings were sometimes isolated from other rings and sometimes juxtaposed on one side or the other of a prismatic ring to form a compound ring (Fig. 2d).

The width of minor rings was 4–9 µm, and they were readily distinguishable by size from major rings, which were 10–46 µm across. Brown rings were 10–15 µm across and were visible even under low-power optical microscopy by their honey color. They could be confused easily with compound rings.

Mean laminar thickness measured along transects running transverse to the rings varied in a cyclic manner between rings. A plot of the change in the thickness of laminae along a transect (Fig. 3a) shows a decline in thickness soon after deposition of the ring and a later increase prior to deposition of the next ring. This pattern was repeated between rings and was the typical pattern in the sections examined. The thickness of laminae was significantly correlated with sea temperature, assuming that the rings were laid down in mid-summer (see below). The highest correlations occurred when a lag period of 1 mo ($r = 0.59$; $P < 0.001$) or 2 mo ($r = 0.69$; $P < 0.001$) were applied to sea temperature data.

We also examined a parasitized shell in which a brown ring and two compound rings were present. Assuming the same relationship with temperature, we estimated the timing of ring deposition from the laminar thickness. The results (Fig. 3b) show that the brown ring interrupted the pattern of seasonally changing thickness of laminae, which is consistent with our conclusion that they are adventitious. In this shell, the highest correlation between temperature and laminar thickness occurred with a lag period of 2 mo for sea temperature ($r = 0.67$; $P < 0.001$) compared with $r = 0.64$ ($P < 0.001$) for a 1-mo lag period and $r = 0.43$ ($P < 0.05$) with no lag.

Ring Deposition

At low magnification, horizontal and vertical sections of the shell show distinct growth rings. Shells of 13–28 mm SL were considered to be 1-y-olds (see below), and a proportion of them showed a fine outer ring (termed minor ring) as well as the sub-

TABLE 2.

Lengths to growth checks SL_1, SL_2, SL_3, and SL_4 for shells of *H. kamtschatkana* at six sites.

Site	*N*	SL_1 (SE)	*N*	SL_2 (SE)	*N*	SL_3 (SE)	*N*	SL_4 (SE)	Mean Growth Rate SE (mm/y)
Gravina Island	26	12.0 (0.5)	39	27.5 (0.4)	40	42.7 (0.6)	28	57.5 (0.9)	15.1 (0.2)
Magic Island	27	11.4 (0.6)	29	26.1 (0.8)	23	44.6 (0.6)	18	61.4 (0.6)	16.9 (0.5)
Thimble Cove	42	11.5 (0.3)	42	26.2 (0.5)	28	41.6 (0.6)	12	56.3 (1.1)	15.0 (0.1)
Galankin Island	13	11.8 (0.5)	11	27.6 (0.9)	13	44.1 (0.9)	13	57.8 (0.9)	15.5 (0.4)
Ridge Island	22	10.9 (0.4)	46	26.6 (0.5)	52	42.5 (0.5)	31	55.3 (0.8)	14.9 (0.5)
Battery Island	3	14.0 (1.7)	6	25.5 (1.1)	8	47.1 (1.1)	8	61.4 (1.0)	16.4 (1.3)

Mean values		11.9 (0.4)		26.4 (0.3)		43.3 (0.8)		57.6 (1.1)	15.4 (0.4)

Individual lengths are not independent within a site because individual shells have multiple growth checks.

sequent thicker rings (termed major or prismatic rings). In *H. kamtschatkana*, the spire is unusually elevated some 2–5 mm above the surrounding shell, compared with Australian or Mexican species (unpublished observations) and, hence, more susceptible to erosion than those species. The incidence of minor rings did not decline in shells to a presumed age of about 4 y but thereafter declined rapidly, and none were seen in shells > 5 y old. We presume that the decline in their incidence was due to erosion, because with increasing age the minor ring disappeared from the face of the horizontal section but could still be seen on the eroded lateral margin of the spire.

The incidence of separate minor rings also varied between sites. At Galankin Island, 62% of shells had minor rings, and at Magic Island, 48%, but at Thimble Cove, 17%, at Ridge Island, 13%, and at Gravina Island only 2% had minor rings. It is possible, of course, that minor rings may have occurred juxtaposed to their neighboring major rings (Fig. 2a), in which case we would not have distinguished them. As some presumptive 1-y-old shells had both a distinct minor and a major ring, we concluded that both were laid down in the first year, the minor ring possibly during the first winter when the first growth check was deposited (see below). We examined a sample of presumptive 1-y-old shells from the two sites with the largest proportions of shells with minor rings to see if deposition of a distinct minor ring was related to length. The mean length of shells that deposited a distinct minor ring was 21.0 mm (SE 1.6 mm), and of those that did not, was 15.2 mm (SE 1.1 mm). The differences were significant ($t = 2.4$; $P < 0.05$). This suggests that individuals, which either grew faster or settled earlier in the summer (or both), were more likely to lay down a distinct minor ring than those that grew more slowly or settled later. As the presence of minor rings was variable, and they were in any event superfluous for aging, we excluded them from further consideration.

Examination of the shell nacre on the ventral surface at the spire indicated whether nacre or a ring (visible as an opaque layer with a nonreflective surface) was the last layer deposited there. In all, at four sites 91.4% of shells ($N = 358$) had most recently deposited a ring over a broad area near the spire. In the remaining cases, some nacre had been more recently laid down at the spire. We concluded that a ring must have been laid down during the last episode of shell deposition before the collection of the samples in mid to late July at all our sites.

A practical problem that we experienced in estimating the age of juvenile shells from ring counts, mainly at the Magic Island and Thimble Cove sites, was the difficulty in distinguishing minor from major rings. Thus, it was possible to interpret a shell with two rings as a 1-y-old with a minor ring or a 2-y-old without one. The presence of two growth checks (see below) in 2-y-old shells helped to resolve this dilemma. Another problem was ambiguity in ring counts. This happened where two rings merged or where there were false rings, i.e., where one ring divided into two and then merged again into one (see Fig. 1d in Shepherd et al. 1995). In these cases of uncertainty as to whether there was one or two rings (6% of all shells), the ring count was revised in the light of the number of growth checks observed. In another 2% of all shells examined, there was a clear discrepancy of 1 year in age estimated from ring counts and from growth checks. In these cases, we adopted the ring count for the purpose of the regressions, although they were not consistent with the counts of growth checks. In very few cases (1.4% of all shells), the exposed section was milky, and no rings were visible.

The growth rate of many species of abalone is linear or nearly so for the first 3–5 y of life, and thereafter is curvilinear. The linear phase can be fitted with a linear regression, and the curvilinear phase with a von Bertalanffy curve (Shepherd and Hearn 1983). Hence, a regression of SL versus the number of rings during the linear phase of growth will give an estimate of the rate of deposition of rings with age if the growth rate is known (Shepherd and Triantafillos 1997).

Plots of length versus number of rings showed a linear or nearly linear relation with length to about 80 mm SL at each site after which the curve approaches an asymptote as expected for von Bertalanffy growth. Linear regressions were fitted to data for each site for the linear phase of growth. The regression equations are given in Table 3 and are plotted in Figure 4 for those sites where we found the most juveniles. The deposition rate of rings with length was similar at all sites. Assuming that the deposition rate of rings is age-related, then the growth rate appears to be fastest at Magic Island and Jumbo Island and slowest at Gravina Island.

Mark-recapture data from Gravina Island over the initial length range of 45–75 mm SL (Fig. 5) show that the growth rate declined linearly from about 15 mm/y at 50 mm SL to about 5 mm/y at 75 mm SL (Woodby et al. in press). The mean growth rate of marked individuals over this length range was 10.3 mm/y (SE 0.9 mm/y). This is close to the mean growth rate of 11.1 mm/y (SE 0.7 mm/y) given in Table 3 for Gravina Island. Although the two estimates cannot be compared statistically, their SEs overlap, suggesting that they are not significantly different. Tagged abalone at Gravina Island showed von Bertalanffy rather than linear growth (Fig. 5), which is inconsistent with our hypothesis of linear juvenile growth rate and with our analysis of length-frequency data. This incon-

TABLE 3.

The seven sampling sites, with regression equations of SL versus number of major rings (R) of *H. kamtschatkana* for all shells <80 mm SL.[a]

Site	*N*	Regression Equation (SE)	R^2	Length at Age 1 y (mm)	Brown Rings (%)

[a] Estimated mean growth rates and length at a presumed age of 1 y were derived fom the regression equations. The mean incidence of brown rings in shells >70 mm SL are given for each site. The slope of the regression equation is the mean annual growth rate (mm per year).

sistency could be an artifact of insufficient recaptures of tagged abalone that were tagged at < 50 mm SL.

Length-frequency distributions for four sites are shown in Figure 6 with Gaussian curves fitted to the prominent modes. Linear regressions of modal means versus presumptive age gave estimates of the mean growth rates (Table 1). These were 13–19 mm/y, and length at 1 y of age was 16–23 mm, according to the site. High R^2 values of > 0.99 for every site indicate that the growth rate was uniform and very nearly linear. The two sets of estimates of growth rates for the four sites, summarized in Tables 1 and 3, were very close with overlapping SEs, so we accepted that one ring per year was laid down at these sites. Mean lengths at one ring (Table 3) and at 1 y (Table 1) were also very close (we found no 1-y-olds at Gravina Island), which is consistent with the hypothesis that one ring per year is deposited.

Growth curves for all length-age couplets for each site and for all sites combined are given in Table 4. Length-age couplets and a growth curve for all sites combined are plotted in Figure 9.

Brown Rings and Shell Erosion

As shown by SEM micrographs and energy-dispersive spectroscopy, brown rings are qualitatively different in structure and composition from prismatic rings. An examination of a series of vertical sections showed that brown rings were laid down only in the presence of infestation by endobionts and that the number of brown rings increased with increasing infestation. Further, they appeared to have been laid down independently of the usual regular pattern of deposition of prismatic rings, and so they were considered adventitious when alone rather than substitutional for a prismatic ring. Accordingly, we excluded brown rings from the count of rings for the purpose of aging shells when they occurred alone but not when they occurred as compound rings, i.e., when they were juxtaposed to a prismatic ring. Shepherd and Huchette (1997) similarly found that brown rings in *Haliotis scalaris* were adventitious. In horizontal sections, brown rings were usually rec-

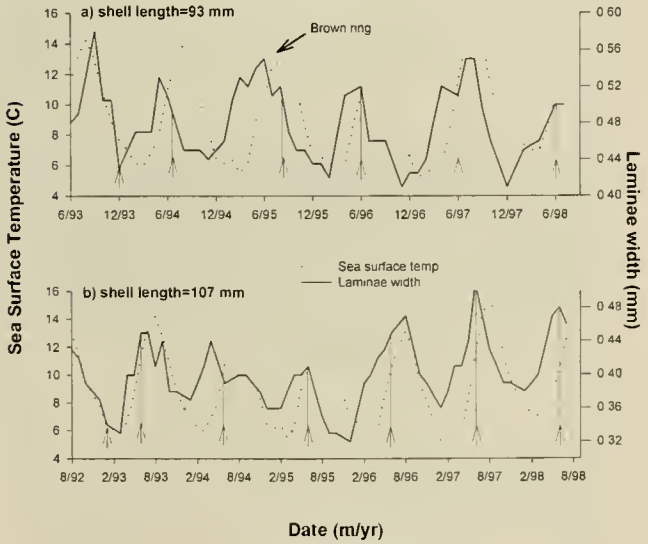

Figure 3. Change in laminar width in vertical sections in the spire of *H. kamtschatkana* for: a) a 5-y-old shell (93 mm SL) that had a brown ring between the first and second major rings, and b) a 6-y-old shell (107 mm SL). Arrows indicate the location of rings in the sequences, and the first arrow in each sequence is a minor ring.

ognizable because the process of grinding and polishing caused cavities on the surface where the softer organic material was preferentially excavated.

Brown rings were rarely present in shells < 70 mm SL. Above

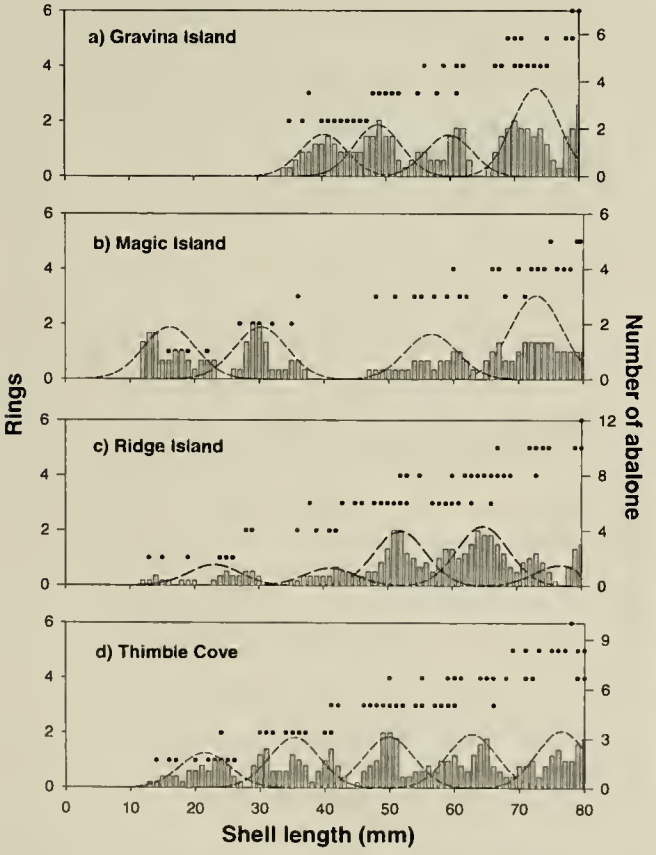

Figure. 6. Plots of length-frequency data (vertical bars are running means of 3-mm size intervals), rings at length (solid circles) and Gaussian modes fitted by EMMIX (dashed lines). Modal means are: a) Gravina Island: 40.3, 48.7, 59.8, and 73.3 mm, variance 13.0 mm; (b) Magic Island: 16.3, 30.5,56.6, and 72.7 mm, variance 16.1; c) Ridge Island: 23.1,41.0, 52.0, 64.8, and 76.7 mm, variance 15.8; and d) Thimble Cove: 21.5, 35.3, 49.9, 62.7, and 76.5 mm, variance 14.9.

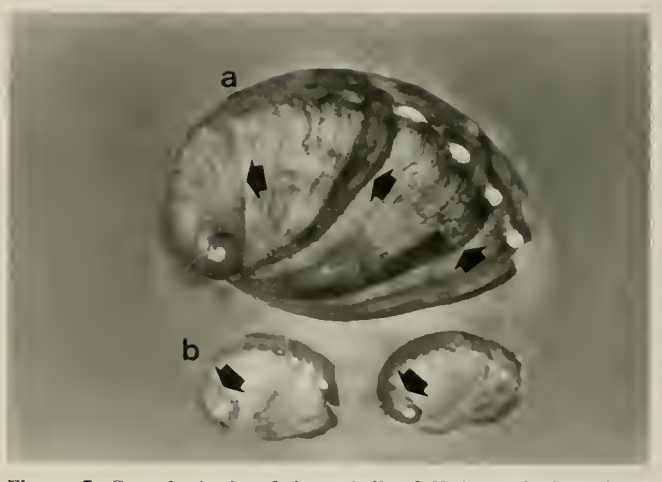

Figure. 7. Growth checks of three shells of *H. kamtschatkana* from Thimble Cove seen by transmitted light. A) SL = 66 mm. Three checks indicated by arrows. a) SL_1 not visible; SL_2 = 28 mm; SL_3 = 42 and 46 mm (a typical double check); and SL_4 = 60 mm. B) SL = 25 mm (left); and SL = 26 mm (right). For both shells $SL_1 \approx 10$ mm (indicated by arrows) and $SL_2 \approx 25$ mm (faintly visible at the edge of the shell).

that size, the incidence of brown rings in the spire sections of shells in samples varied from 13–33% according to site (Table 3). Overall, however, only 3% of shells > 70 mm SL were unreadable because of the effect of parasites alone or were compounded by erosion of the shell.

Shell erosion was slight (2–5%) at our study sites, which were all in places sheltered from ocean swell. Generally, erosion of the shell was associated with attacks by parasitic endobionts, which were provisionally identified as polydorid annelids, and occasionally the bivalve, *Penitella* sp., which caused excavations around the elevated spire. In most cases, the eroded rings could still be seen and counted, not in the horizontal section, but at the eroded margin of the spire near the prominent suture line that joins the older shell with the later deposited shell.

Growth Checks

Growth checks, which are lines marking an interruption in shell growth, were characterized by at least one, but usually more, of the

Figure. 8. Lateral view of two shells of *H. kamtschatkana* showing a suture line in the shell that marks a growth check continuing below the line of pore-holes to the margin of the shell. a) SL = 50 mm (SL_2 indicated by arrow). b) SL = 41 mm (SL_2 indicated by arrow).

following features as seen by transmitted light (Fig. 7): a ridge up to 0.5 mm high dorsally on the shell; and a fine suture line in the shell or a discontinuity in the pattern of pigmentation or sculpture of the shell. The growth checks were apparently formed at the growing margin of the shell at the time of interruption to shell growth. The growth check continued past the pore-holes to the margin of the shell where the discontinuity or ridge was often more conspicuous (unless eroded) than elsewhere (Fig. 8). The first check, SL_1, is lost almost always by age 3 y, and the next check, SL_2, is lost a year later as new nacre is deposited on the ventral surface of the shell, preventing transmission of light through the shell. Checks SL_3 and SL_4 are often visible dorsally only as discontinuities in the shell.

The estimation of age from growth checks alone has some limitations or ambiguities. In 8% of the shells that are > 5 y old, one or more checks were missing, apart from the incremental loss of the earliest ones. In 6% of the shells over the same age range, dual growth checks, i.e., two checks very close together, were seen, most often at Sl_2 and SL_3. In these cases, we measured length to the check that persisted to the shell margin or to the former of the two checks, if they were indistinguishable. In about 1% of the shells, no checks could be seen at all.

The mean lengths at which the growth checks SL_1–SL_4 were laid down are given in Table 2. These were compared to estimates of the lengths at age 1 y from the regressions in Table 1 for the four sites listed and from the mean length of shells with one ring for Galankin Island. For these five sites, a mean value of 60% of the first year's growth was achieved before the growth check was laid down, declining to a mean of 41% in the fourth year. The decline was not significant ($t = 0.20$). Overall, for the five sites 53% of the annual growth during the first 4 y was achieved before deposition of the growth check for the respective year. Assuming a uniform birth date in July, we conclude that the growth check was laid down about half way through the year, i.e., in about January, which is about mid-winter with minimal sea temperatures.

The mean lengths at which growth checks were laid down (Table 2) are very nearly linear with age ($r^2 > 0.99$ for all five sites), indicating a linear growth over the length range of ~10–60 mm SL. The growth rates derived from growth check analysis (Table 2) are highly correlated with those calculated from ring analysis (Table 3) ($r = 0.88$; $P < 0.01$), and the mean growth rates for all sites combined derived from the two independent methods did not differ significantly ($t = 1.24$). The consistency in growth rates between the ring and growth check analyses supports the hypothesis that growth checks are deposited annually.

TABLE 4.

Parameters of von Bertalanffy growth curves fitted to length-age data for each site.

Site	*N*	K (SE)	L_∞ (SE)
Gravina Island	86	0.21 (0.02)	119.7 (5.6)
Magic Island	103	0.20 (0.01)	129.6 (4.4)
Thimble Cove	110	0.16 (0.01)	136.9 (7.7)
Galankin Island	41	0.22 (0.03)	113.0 (7.7)
Ridge Island	79	0.16 (0.02)	134.9 (13.7)
Battery Island	32	0.25 (0.02)	118.9 (4.2)
Jumbo Island	58	0.19 (0.02)	128.6 (5.5)
Mean value		0.20 (0.01)	125.9 (3.4)
All sites combined	509	0.18 (0.01)	131.9 (2.4)

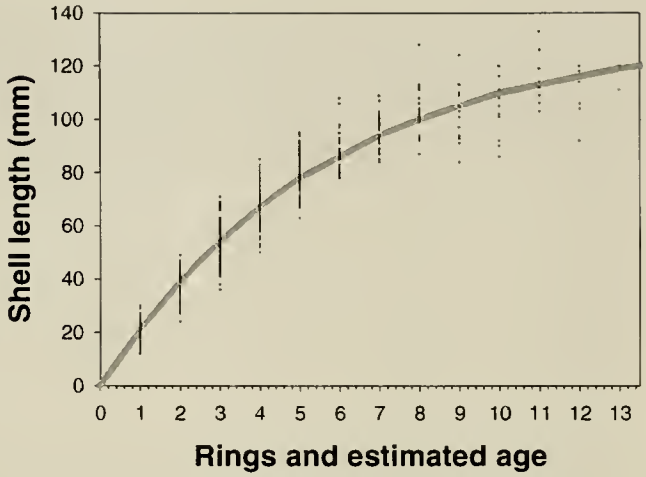

Figure. 9. A plot of a von Bertalanffy growth curve fitted to length-at-age data for all sites combined, and length-increment data from Gravina Island.

The number of rings and growth checks present in shells of known or estimated age are given in Table 5. Of the seven shells of known age, three were eroded and/or parasitized at the spire and the rings could not be counted. The remaining four deposited a mean number of 1.03 rings per year (SE 0.02 rings per year), after deducting the number of brown rings, over a mean period of 14.5 y/shell. The seven shells also laid down an estimated 0.92 growth checks per year. The two shells from British Columbia each laid down an estimated five rings during the 5 y between tagging and recapture, but growth checks were not visible in these shells.

DISCUSSION

Microstructure

The microstructure and pattern of changes in thickness of aragonitic laminae show striking similarity to those of *Haliotis corrugata* and *Haliotis fulgens* Phillipi. The block-like prisms and the brown rings (described by Shepherd and Avalos-Borja 1997 as being of granular structure) are similar in the three species, although in *H. corrugata* the rings were compound, with prismatic rings and brown rings regularly juxtaposed. The similarity between the three species is perhaps not surprising, given their recent common ancestry (Brown 1993, Lee and Vacquier 1995).

The cyclic change in the thickness of the laminae between rings and the correlations with temperature provide internal corroborative evidence that laminar thickness is temperature-dependent and, hence, that ring deposition is annual. The significance (if any) of the 1–2-mo lag correlation is unclear. We arbitrarily assumed that laminar deposition occurred continuously throughout the year. If, however, there was a pause in laminar deposition for 1–2 mo after sea temperature reached a maximum, as could happen around the time of spawning, then an apparent lag would be observed. This question cannot be resolved until laminar deposition can be accurately pinpointed in time as with a time stamp (see Hawkes et al. 1996). The dependence of laminar thickness on temperature has been previously noted for the abalone *H. corrugata* (Shepherd and Avalos-Borja 1997) and *H. fulgens* (Shepherd et al. 1995), as well as some bivalves (reviewed by Lutz and Rhoads 1980). The effect is analogous to the control of width of tree rings by air temperatures (Briffa et al. 1995) and to the differential density banding in

TABLE 5.

Number of rings and growth checks in shells of *H. kamtschatkana* of known or estimated age.[a]

Shell Length (mm)	Age (y)	No. of Rings	No. of Checks (Inferred + Counted)	Comments
103	10	10	4 + 8	Two extra brown rings excluded
103	12	12	1 + 12	Two extra brown rings excluded
106	15	8?	2 + 12	Spire partly destroyed by erosion and parasites
98	17	18	3 + 10	Two extra brown rings excluded. Eroded in part
96	18	13?	2 + 11	One extra brown ring excluded. Spire partly destroyed
98	19		2 + 17	Spire completely destroyed
102	19	20	2 + 15	Two extra brown rings excluded
99[b]	10.2 ± 0.3	10		Shell from Dempster Island, B.C.
114[b]	10.8 ± 0.3	11		Shell from Dempster Island, B.C., remnants of two rings seen at eroded margin of spire near suture line

[a] The first seven shells were held in aquaria at Seward, Alaska until they died. The presence of growth checks (where not visible in the expected position to age 3.5 years) was inferred; i.e. 4 + 8 means 4 rings were inferred and 8 later ones counted.
[b] Both tagged abalone at liberty for 5 y. Age at tagging was estimated from a mean growth rate of 15.9 mm/y derived from the regression of the number of rings versus SL for a sample of shells ($N = 21$) from the tagging site, assuming that one ring per year was laid down.

corals due to seasonal sea-temperature changes (Dodge and Lang 1983).

Shell Aging

A number of studies have shown that rings can be reliably used to age the shell of various species of abalone (Prince et al. 1988, Erasmus et al. 1994, Shepherd et al. 1995a, Shepherd et al. 1995b, Shepherd and Avalos-Borja 1997, Shepherd and Huchette 1997, Shepherd and Triantafillos 1997, Shepherd and Turrubiates 1997). On the other hand, only four species are known to lay down growth checks that are useful for aging (reviewed by Day and Fleming 1992, Shepherd et al. 1995b). Previously Shepherd and co-authors (cited above) have considered that ring counts may not give a precise age for each individual shell due to apparent random variability in the deposition rates between individuals, although they do give a valid estimate for a population. The low incidence of clear inconsistency (~2%) in estimates of age between the two methods increases confidence in each and suggests that the rate of deposition of rings is relatively precise for individuals of this species, although slight ambiguity in interpreting structures exists with both methods. Thus, ring deposition satisfies the criteria proposed by Day and Fleming (1992) that deposition rates must be consistent and that deposition is at about the same time each year. Similarly, in species that lay down growth checks, a small percentage of shells fail to do so in any year. The use of both methods in the pinto abalone has the advantage that each method provides an independent test of the accuracy of the other, since both rings and growth checks are laid down according to different external cues.

On the question of whether horizontal or vertical sections at the shell spire give better readings, we note that, although the two kinds of section show spatial effects in different planes, the readings from each are comparable (see Shepherd et al. 1995). We prefer horizontal sections for the practical advantages of ease of preparation and reading (especially fine rings). An advantage of vertical sections is that brown and compound rings are more easily distinguishable under higher magnification.

Rings appear to be laid down during maximum summer temperatures or spawning (or both) as Shepherd and co-workers have found for Mexican and Australian species. Conversely, growth checks are apparently deposited during minimum temperatures, as is known for other cold-temperate species (Forster 1967, Sakai 1960, Poore 1972) and one curious subtropical species (Shepherd et al. 1995b).

The exclusion of brown rings from counts for aging purposes is rarely problematic. Brown rings can most readily be distinguished in horizontal sections by the cavities that commonly surround them (caused by the rasping process, which preferentially excavates softer organic matter) and by their rupture of the pattern of deposition of rings. Color alone is ambiguous because of the frequent occurrence of brown rings in juxtaposition to prismatic rings at least over some part of the length of the latter. Usually, the prismatic and organic elements of a compound ring can be seen at about ×20 magnification or more.

We do not exclude the possibility of using growth checks to estimate the age of shells > ~4 y, but we simply point out that ambiguity in identifying checks seems to increase with age and may nullify the benefit of an independent aging method. We note that a few shells of known age had fewer than the predicted number of growth checks (Table 5), suggesting the possibility of some bias. We also observed that growth checks were less conspicuous in shells from British Columbia than in those from Alaska. Possibly higher sea-temperature minima in British Columbia cause a briefer recession or no cessation of winter growth. Another source of bias in aging abalone is through the (usually) combined effect of parasites, which cause deposition of brown rings, and shell erosion. This was not problematic in this study because few pinto shells had brown rings in the length range of interest.

Growth Rates

Our study provides the most detailed information on the growth of the pinto abalone in Alaskan waters. The growth rate of this abalone is poorly known in the first 4 y of life but is better known for older individuals in British Columbia waters (reviewed by Sloan and Breen 1988). Paul et al. (1977, Fig. 4) estimated a growth rate of ~17 mm/y in the laboratory for individuals maintained at 12–15°C, a rate later confirmed in the laboratory by Sloan and Breen (1988). The latter authors presented an equation relating the growth rate of 30 mm SL abalone with water temperature. The mean annual sea surface temperature range at Sitka is ~4.5–14°C (Standley 1987), and the monthly mean is 8.2°C. This would be somewhat higher than the mean temperature at 5–10 m depth

where this abalone lives. Application of their formula gives a mean growth rate of 18.0 mm/y, which is slightly greater than those found in this study. A study by Larson and Blankenbeckler (1980), which is cited in Sloan and Breen (1988), found that the growth rate decreased with increasing size. Annual length increments averaged 19.1 mm for individuals having < 50 mm SL, 12.6 mm for those of 50–74 mm SL, 6.2 mm for those of 75–99 mm SL, and 4.3 for those of > 100 mm SL. Quayle (1971) estimated that the pinto abalone had a 35-mm SL at age 2 y and thereafter grew at a rate of 10 mm/y. Fournier and Breen (1983) estimated that growth rates from 1–5 y ranged from 11–16 mm/y at two sites; these estimates were based on the decomposition of "snapshot" length-frequency data into annual modes. Our data are more accurate than these estimates but are within the same range.

Like Fournier and Breen (1983), we do not have direct information on the growth rate of this species in the first year. An alternative hypothesis is that the initial mode we found is of 2-y-old abalone. We discount this possibility because of known laboratory growth rates in the first year cited above, and also because we could detect animals down to at least 10 mm SL on crustose corallines. If another mode were present, we should have seen it.

Von Bertalanffy growth parameters for Alaskan abalone are remarkably close to those in British Columbia. Sloan and Breen (1988) reviewed growth at nine sites in British Columbia. Excluding the values for Lyell Island because there were few tag recoveries there, they recorded for eight sites a mean K value of 0.24 (range 0.16–0.24) and a mean L_∞ value of 120.1 mm (range 95.2–137.3 mm) compared with our mean K value of 0.20 and L_∞ value of 126.7 mm for seven sites (Table 4). While the two sets of values are not strictly comparable because the values of Sloan and Breen are derived from length-increment data, whereas ours are from length-at-age data (see review of Day and Fleming 1992), they clearly show close similarity.

What is the cause of the differences in growth between sites? Breen (1980) considered that the growth rate of the pinto abalone was related to the food supply. Abalone in sheltered to semiexposed habitat in *Macrocystis* or *Nereocystis* forests grew faster and to a larger size than those in habitats dominated by the unpalatable kelp *Pterygophora* and exposed to ocean swell. All of our sites were in moderately to highly sheltered habitats, usually in places of moderate tidal current. The habitats were variously dominated by *Macrocystis*, *Nereocystis*, *Agarum* and *Laminaria* cf *saccharina*. Grant Cove at the northern end of Gravina Island was exposed to local seas to the north, and Jumbo Island, far up Hetta Inlet, was the most sheltered. There was little variation in growth between our sites, and we attribute this to the overall similarity of habitat.

Ring counting is an appealing alternative to tag-and-recapture methods for obtaining growth rates, which are important for regulating fisheries (Troynikov and Gorfine 1998). Ring counting is cost-effective, requiring only one sampling event, and does not negatively affect growth as tags may (reviewed by Day and Fleming 1992). Ring counting also provides length-at-age data, and not simply increments at size, and, with catch-curve analysis can provide estimates of the total mortality rate of a population. The present application has provided the first broad geographic depiction of abalone growth rates in Alaska. These data are an important component of the stock assessment program that must precede any future reopening of the Alaskan fishery after its collapse in the past 2 decades (Woodby et al. in press).

ACKNOWLEDGMENTS

The first author is grateful to the Alaska Department of Fish and Game for the provision of accommodations, facilities, and logistic support during his stay in Alaska and to Centro de Ciencias de la Materia Condensada for the provision of accommodations and laboratory facilities at Ensenada, Mexico. Dr. H. Echavarria kindly provided computing facilities at Centro de Investigacion Cientifica y Escuela Superior de Educacion. We thank Robert Larson, Craig Sempert, Scott Walker, Marc Pritchett, Kyle Hebert, and Dave Barto for diving assistance, Tom Brookover for field assistance, Peter Hagen and Kristen Munk for technical advice, and Cori Cashen for preparation of Figure 1. Israel Gradilla gave generously of his time for SEM studies and took the micrographs in Figure 4, and G. Vilchis took the photographs in Figures 3 and 8. Dr. A. J. Paul of Seward Marine Centre made available shells for aging, and Dr. A. Campbell provided shells from British Columbia. Dr. Rob Day and referees helpfully criticized the manuscript.

ABSTRACT A study of the presence of the freshwater mussel *Limnoperna fortunei* in the diet of the native fish *Leporinus obtusidens* was performed in Costanera Norte, Buenos Aires. Fish were collected monthly for a 1-year period to analyze their digestive tracts. From a total of 157 fish collected (20–55 cm total length), 21 had empty digestive tracts. Of the remaining 136 individuals, 98 (72.1%) contained fragments of *Limnoperna* shells. The mussel represented 14.5% of the stomach content dry weight and 44.4% of the intestinal content dry weight. *Limnoperna* was present in almost all fish over 30 cm (total length). The largest number of mussels ingested by a *Leporinus* individual was 77, estimated by mussel beak count. Mussels 15–20 mm in shell length to be the most abundant in *Leporinus* digestive tract.

KEY WORDS: Invasive mussel, *Limnoperna* control, fish predation

INTRODUCTION

Limnoperna fortunei(Dunker 1857) arrived in Río de la Plata, Argentina, in the early 1990s (Pastorino et al. 1993). The mussel attaches to any available hard substrate using byssal threads and can form dense aggregations. The rapid expansion and the high densities achieved in the Rio de la Plata and the Paraná basin (80.000 individuals per square meter recorded in 1993, Darrigran and Pastorino 1995; and more than 100.000 in 1995, Darrigran et al. 1998) give the impression that *L. fortunei* has not encountered local competitors, predators, or parasites.

A counter example is the Zebra mussel, *Dreissena polymorpha* (Pallas 1754), which invaded North America in the mid- 1980s. In laboratory conditions small Zebra mussels (< 8 mm in shell length) are preyed upon by Crayfish (Love and Savino 1993, MacIsaac 1994), and by the blue crab in estuarine conditions (Molloy et al. 1994). Several fish have been reported as significant predators of the Zebra mussel (French and Bur 1993, Marsden 1997, Tucker et al. 1996).

In Argentina, Darrigran and Colauti (1994) reported the importance of the native fish *Pterodoras granulosus* (Valenciennes 1833) as a predator on *Corbicula fluminea* (Müller 1774), another invasive freshwater species.

To identify possible predators of *Limnoperna fortunei* in the Río de la Plata, an analysis of fish gut contents caught in Costanera Norte, Buenos Aires was performed. Preliminary results showed that native *Leporinus obtusidens*, as well as being the dominant catch was a relevant predator of *Limnoperna fortunei* (Penchaszadeh et al. 1998). This paper is a specific study of the presence of the *L. fortunei* in the diet of *L. obtusidens*.

Leporinus obtusidens ("boga" is the common local name) has a small conic head, rounded snout, well-developed lips, and small frontal teeth in the mouth. Each maxillary has a single row of chisel-shaped teeth pointing forward, the two anterior being longer than the others: the name of the genus refers to this characteristic, this kind of dentition is reminiscent of leporinid rodents.

MATERIAL AND METHODS

Fish were collected form sports fishermen from March 1998 to February 1999 in Costanera Norte, Rio de la Plata, 34°34′S, 58°23′W; a location heavily colonized by *Limnoperna*. The tidal regime is mixed, although predominantly semidiurnal with a tidal range of 0.63 to 1.07 m. Water levels and currents are strongly influenced by meteorological conditions, mainly wind direction and intensity, the most important of which is the "Sudestada." This is characterized by a gradual and persistent increase in wind speed blowing from the SE to the SSE, during which time, winds can pick up to around 25 m/sec (Guerrero et al. 1997). Heavy rain in the Parana basin can also strongly influence water levels. Mean surface water temperature values for Costanera Norte are: summer (January to March) 24.07 ± 2.01 °C; fall (April to June) 13.83 ± 4.68; winter (July to September) 14.63 ± 2.00 and spring (October to December) 21.04 ± 0.11.

Fish length was measured to the nearest 1 cm and then dissected *in situ*. The entire digestive tract was removed and preserved in a 10% formalin solution. In the laboratory, stomach and intestine contents of each *Leporinus* were analyzed under a dissecting microscope and separated into *Limnoperna* shells and other material. Then, the dry weight (80 °C until constant weight was achieved) of the two groups was taken.

Limnoperna beaks (anterior portion of the valve containing the umbonal region) were counted, the total number then divided by two was the estimated number of *Limnoperna* contained in each fish. To estimate the length of the mussels consumed, *Limnoperna* individuals were collected from the same fishing site in January, 1999. These mussels were then measured and separated into four size ranges. Ten mussels from each category were weighed, and a proportion of shell length to shell weight was obtained for each category. The total shell weight in the digestive tract of each fish was then divided by the number of *Limnoperna* eaten, estimated by the beak count.

RESULTS

Of the 157 *Leporinus* analyzed, the digestive tracts of 21 were empty. Of the remaining 136 individuals, 98 (72.1%) had fragments of *Limnoperna* shells in the stomach, the intestine, or both (Table 1). *Limnoperna* shells represented 14.5% of the stomach content dry weight and 44.4% of the intestinal content dry weight. Considering the entire digestive tract, 33.4% of the content dry weight was *Limnoperna* shells. The digestive tracts did not show damage or bleeding, although they were sometimes fully packed with shell fragments.

Limnoperna was present in the diet of *Leporinus* during almost the entire year of sampling. Lowest values occurred during winter (June–August) when mussel shells were found in only 40, 14, and 0% of analyzed fish, respectively (Table 1). Winter was also the season of lowest *Leporinus* catch in the study area.

Except for six individuals, *Limnoperna* was present in all fish (47) over 30 cm (total length) with material in their digestive tract. The presence of *Limnoperna* in the *Leporinus* digestive tract was maximum during the period from October to February (83 to 100%).

The largest number of mussels ingested by a *Leporinus* individual was 77 (beak count method). According to the shell length–weight proportion found (Table 2), the 10 fish with the largest number of ingested mussels contained various sizes of prey. The mean shell weight ranged between 0.012–0.020g (<10 mm of shell length, 20%), 0.03–0.068g (10–15 mm of shell length; 70%) and 0.175 g (15–20 mm of shell length; 10%). These results indicate that *Limnoperna* of between 10–15 mm in shell length were the most abundant in *Leporinus* digestive tract.

In 36 cases, entire *Limnoperna* individuals with unbroken shells and intact soft tissue were found in the digestive tract of *Leporinus*. Mussels measured between 1.5 and 5.7 mm in shell length and fish ranged 26.0 to 33.0 cm (total length).

Aquarium observations (M. Brögger, pers. comm.) show that *Leporinus* do not always remove the entire mussel from its substrate; on several occasions fragmented mussels with the beak area still attached to the substrate were observed. Other mussels >30 mm had bite marks on the periostracum.

DISCUSSION

Before the *Limnoperna* invasion there were few published reports on *Leporinus obtusidens* diet, and almost all of these are confined to the middle Parana river region (Mastrarrigo 1950, De Occhi and Oliveros 1974).

Mastrarrigo (1950) defined the alimentary regime of *Leporinus* as mainly omnivorous, with a high proportion of aquatic vegetation (in the case of at least 72% of the fish analyzed in Rosario, middle Paraná), but also mentioned the presence of a small proportion of fragmented river snails in the gut. Snails were referred to as the main food for *Leporinus* in the Uruguay river (Gualeguaychú, Entre Ríos), where their digestive tracts are often full of shell fragments. Mastrarrigo (1950), commented that local fishermen called them "bogas caracoleras" ("snail-eating bogas").

According to De Occhi and Oliveros (1974), mollusks were present in 32% of the examined *Leporinus* (5% bivalves and 27% gastropods, basically *Helobia* sp.; however, seeds and fruits were always dominant (37%). They believe that in *Leporinus obtusidens* because of the disposition of the pharyngeal teeth, these are used only to crumble soft material, because they lack crushing surfaces; whereas, fragmentation is achieved by action of the oral teeth.

Aquarium observations show that *Leporinus* did not always ingest the entire prey; instead, they bit off only a portion of the mussel (the bivalve was not completely removed from the substrate on many occasions). These observations suggest that there could be a underestimation in the amount of ingested mussels calculated by the beak counting method. This also could lead to an overestimation in the calculated size of ingested mussels.

The weight of *Limnoperna* in the fish digestive tracts could also be underestimated, because the soft material was weighed as a whole (with certain contribution of mussel tissue).

Differences observed in the amount of *Limnoperna* shell found in the stomach content (14.5%) and intestine content (44.0%) could indicate that *Leporinus* is preferentially an early–morning feeder, because all of the studied material was captured between 12:00 m. and 5:00 p.m.

The most abundant *Limnoperna* sizes in *Leporinus* digestive tracts were 10–15 mm in length. According to Boltovskoy and Cataldo (in press), who estimated *Limnoperna* growth in experi-

mental conditions. these sizes correspond to mussels 3 to 6 months old.

The presence of *Limnoperna*, with its extraordinary abundance, occupying a seemingly empty niche in the Plata basin, has introduced a new element in the diet of some fish and constitutes the main food item for *Leporinus obtusidens*. Although other predators have yet to be identified, the "boga" has proved to be an important natural enemy of the invading mussel, *Limnoperna fortunei*.

ACKNOWLEDGMENTS

Our thanks are given to the following persons for their invaluable assistance: Dr. Hugo López, Museo de La Plata, who kindly identified the fish; the sports fishermen who donated their catch; Nora Brignoccoli who helped in the laboratory; Dr. Paula Mikkelsen who had kindly read an earlier version of the manuscript; and Claudia Peñaloza for her English translation. We also thank the two anonymous reviewers who improved upon an earlier version of this paper. Project PICT 07-03453 and Fundación Antorchas, Argentina, partially supported this research.

ABSTRACT We evaluated the behavior and survival of unionid mussels after emersion in air temperatures across a range that is likely to be encountered during status surveys or relocations. Five laboratory tests were performed with pocketbook *Lampsilis cardium* Rafinesque (2 tests), pimpleback *Quadrula pustulosa* Lea (1 test), and spike *Elliptio dilatata* Rafinesque (2 tests) mussels, each conducted in a completely randomized, nested experimental design. For each mussel species (except *Q. pustulosa*), treatments tested included two water temperatures (25 and 10 °C), five air temperatures (ranging within ±20 °C of the water temperature), three aerial exposure durations (15, 30, and 60 min), and a no emersion control. All treatments were duplicated, with 10 organisms per emersion time and aerial exposure temperature (n = 320 mussels per test). Behavioral response (ability to upright) and mortality were measured daily for 14 d postemersion. Both water and aerial exposure temperature (air shock) were important predictors of times to first uprighting. The intensity function of first uprighting differed among species ($P < 0.01$), and there was a significant interaction between *E. dilatata* versus the other species and water temperature ($P < 0.01$). Over-all mussel survival after emersion was high (93%); however, *E. dilatata* experienced significant treatment related mortality at the 25 °C test water, 45 °C aerial exposure temperature. Because of the high incidence of uprighting and survival of mussels in our study, emersion at moderate temperatures (15 to 35 °C) and durations (15 to 60 min) does not seem harmful to mussels, and, therefore, conducting relocations and status surveys under these conditions should not impair mussel survival and over-all success.

KEY WORDS: Unionid mussel, conservation, emersion, temperature, behavior, mortality

INTRODUCTION

The imperiled status of unionid mussels (Williams et al. 1993) has prompted conservation efforts by public and private natural resource agencies that include status surveys, restocking, and relocation. The effects of collection and handling on mussels in field studies are generally considered benign and inconsequential to mussels relative to most threats (construction, zebra mussel infestation, habitat loss). However, Cope and Waller (1995) reviewed the success of relocation projects and found that mortality of mussels after relocation can be significant (>70% in 30% of projects reviewed). Mortality was highest within 1 year of the event, suggesting that effects of collection, handling, and displacement of mussels may be greater than were previously considered. The environmental conditions that mussels experience during collections and surveys may contribute to low survival, but can also be controlled to some extent. Determination of the emersion and thermal tolerances of unionid mussels would provide guidelines on the conditions in which surveys and relocations should occur to enhance mussel survival and over-all success.

Past studies suggest that mussels can tolerate emersion for hours or even days (Byrne and McMahon 1994, Dietz 1974, Holland 1991, Schanzle and Kruze 1994, Waller et al. 1995). However, survival of mussels is related to such environmental conditions during emersion as relative humidity and air temperature. For example, Waller et al. (1995) emersed *Amblema plicata plicata* Say and *Obliquaria reflexa* Rafinesque for a maximum of 8 h and found that mussels had greater survival when handled during the fall (water temperature ~15 °C; air temperatures ranged from 12 to 25 °C) compared to those handled during the spring (water temperature ~23 °C; air temperature ranged from 18 to 29 °C). In the present laboratory study, we augment these data by evaluating a range of extreme air temperatures and water–air thermal differentials. We selected the minimum and maximum water and air temperature and emersion times based on conditions likely to be found in field collecting situations. In addition to survival, the uprighting behavior of mussels after emersion was selected as a potential indicator of emersion stress; presumably, the ability to upright and burrow into the substratum indicates normal functioning. Waller et al. (1999) found significant species and water temperature related differences in the uprighting and movement intensity of four mussel species after displacement. Thus, displacement, coupled with a thermal and emersion challenge, may also produce significant behavioral changes.

In this study, we evaluated the effects of emersion and temperature on the survival and behavior of three mussel species *Lampsilis cardium* Rafinesque (pocketbook), *Quadrula pustulosa* Lea (pimpleback), and *Elliptio dilatata* Rafinesque (spike), and examined the variation in survival and behavioral response within and among the three species. These mussel species represent two subfamilies (Lampsilinae and Ambleminae) and two contrasting life history strategies (long-term and short-term brooders) within the Unionidae. Additionally, *L. cardium* and *Q. pustulosa* served as surrogates for two U.S. Federally Endangered species, the *L.*

higginsi Lea (Higgins' eye) and *Q. fragosa* Conrad (winged mapleleaf), both found in the Upper Mississippi River basin. *Elliptio dilatata* was chosen as a second surrogate for *Q. fragosa*, because too few *Q. pustulosa* were available for testing at low (10 °C) water temperature.

MATERIALS AND METHODS

Test Organisms

Three species of unionid mussels were collected from the Wolf River at Shawano, Shawano County, Wisconsin. Mussels were transported in holding tanks, containing Wolf River water (25 °C), to the Upper Midwest Environmental Sciences Center, in La Crosse, Wisconsin. Holding tank water temperatures were maintained at 25 ± 3 °C (with addition of nonchlorinated ice as needed), and the dissolved oxygen concentration was maintained at >60% saturation with aeration. Water temperature and dissolved oxygen (Yellow Springs Instrument Model 58 oxygen meter) were measured at 1-h intervals. At the laboratory, mussels were placed into submerged cages held in the Black River (water temperature, 27 °C), near La Crosse, Wisconsin until study initiation. The mussel cages (122-cm length × 122-cm wide × 46-cm height) were constructed of angle and strap iron frame with netting (1.9-cm diam. polyethylene) attached to the iron frame by tie wraps and nylon rope. One species of mussel (111 total; density of 75/m^2) was placed into each cage. During collection, transport, and allocation to cages, mussels were continually immersed in river water.

Experimental Design and Exposure System

Five laboratory tests were performed with *L. cardium* (2 tests), *Q. pustulosa* (1 test), and *E. dilatata* (2 tests), each conducted in a completely randomized design as a nested experiment. For each mussel species tested (except *Q. pustulosa*), there were two water temperature treatments (25 and 10 °C), five air temperatures (ranging within ± 20 °C of the water temperature), three aerial exposure duration treatments (15, 30, and 60 min), and a no emersion control treatment (Fig. 1). Because of limited availability, *Q. pustulosa* was tested only at 25 °C, the treatment we assumed to be more lethal. All treatments were duplicated, with 10 organisms per emersion time and temperature (n = 320 mussels/test), for a total of 32 experimental units. Ten mussels were placed into a flow-through, stainless steel tank (61-cm length × 30-cm wide × 36-cm height) containing sand (13 ± 0.5-cm depth) and 42 ± 0.5 L of overlying well water. Each tank was placed into one of six water baths (305-cm length × 84-cm wide × 46-cm height) maintained at the test temperature (10 or 25 ± 1 °C) with a thermostatically controlled, liquid circulation pump (Remcor Model CFF-501, Remcor Products Co., Franklin Park, IL) connected to the water bath. Tanks were aerated to maintain dissolved oxygen concentrations at >60% saturation. The flow rate of water into each tank was 200 mL/min with a turnover rate of seven times per day. The photoperiod was 16-h light and 8-h dark.

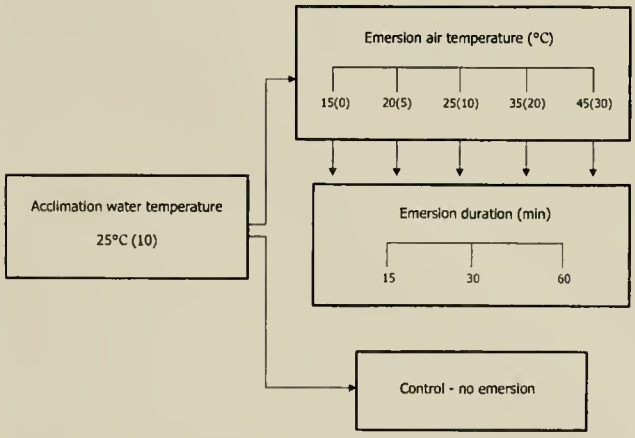

Figure 1. Experimental design for the thermal and emersion exposure tests with three species of unionids. The numbers in parentheses represent the 10 °C test water–aerial exposure regime.

Laboratory tests began when the water temperature of the Black River reached the desired test water temperature (25 °C; July/August and 10 °C; November/December). Each mussel species was tested individually, and a given species was transported in coolers containing Black River water to the laboratory for testing. Ten mussels were randomly selected for each experimental unit. Plastic mesh netting was placed on top of the sand substrate to prevent mussels from burrowing into the substrate before aerial exposure. Mussels were acclimated in their respective tanks at a water temperature of 25 ± 1 °C for 2 d; mussels were not fed during the acclimation period. Mussels within a replicate were numerically marked (1 to 10) on their right valve with a permanent marker. To enable identification of mussels after burrowing into the substrate, each mussel was uniquely tagged with a numbered fishing bobber (3.81-mm dia.) that was attached to a 22.9-cm piece of cotton thread and secured to the umbonal region of the right valve with cyanoacrylate (Krazy Glue® Gel, Borden, Inc., Columbus, OH). Both siphons (incurrent and excurrent) remained immersed while bobbers were being attached to the shells; total handling time was less than 3 min per mussel.

For each treatment, 20 mussels (10 from each replicate) were removed from the test water (25 or 10 °C), transported in water (held at test temperature), and placed into an environmental chamber (Hotpack® Biological Chamber, Hotpack Corp., Philadelphia, PA) at a given air temperature (25 °C water temperature; 15, 20, 25, 35, 45 °C air temperature; 10 °C water temperature; 0, 5, 10, 20, 30 °C air temperature) for a duration of 15, 30, or 60 min. Treatments were conducted in order of increasing air temperature and emersion duration. The target relative humidity in the environmental chambers was 60 ± 5%. This relative humidity was selected based on average ambient air conditions experienced in our geographic region (Steve Thompson, National Oceanic Atmospheric Administration, La Crosse, WI, pers. comm.). Following emersion, mussels were removed from the environmental chamber, transported in well water (held at the test temperature, 25 or 10 °C), and returned to their respective tanks. Each mussel was placed directly on top of the sand substrate, with the right valve (tagged side) facing upward. Test organisms were fed a mixture of C4 algae diet (Coast Seafoods Co., South Bend, WA; 0.2 mL per mussel) and dry *Chorella* (0.013 g dry weight per mussel) daily. Mussels were monitored for mortality and uprighting response for 14 d postemersion. At test termination (14 d postemersion), mussels were recovered from each tank and measured for total length and whole mussel wet weight. Sex of *L. cardium* was determined by shell dimorphism. *Elliptio dilatata* and *Q. pustulosa* are not sexually dimorphic; thus, we examined histological sections of half of the mussels from each replicate in the 25 °C test to determine the sex ratio, and assumed animals tested at the 10 °C water temperature had a similar sex ratio, because all mussels came from the same population and were randomly sampled.

Statistical Analyses

For each mussel species, we examined patterns between two response variables, times to first uprighting and death, as a function of water temperature (°C), duration of aerial exposure, and air shock temperature (°C), which we define as the difference between water temperature and air emersion temperature. We refer to both first uprighting and death as events, and our primary data consist of elapsed times to occurrences of those events for each mussel. Some event durations may have exceeded the study duration (14 d) and, therefore, went unobserved; these events are said to be "right-censored" (Hosmer and Lemeshow 1999). Proper accommodation of censoring is critical to valid interpretation of time-to-event data. For both events (first uprighting and death), we used the Cox proportional hazards regression model (Cox 1972, Newman 1995, Hosmer and Lemeshow 1999) to identify factors that explained the pattern in uprighting and survival. We arbitrarily selected *L. cardium* as the baseline species for our analysis; this choice does not affect the over-all results. The baseline temperature was 0 °C, and other temperatures were coded as deviations from this baseline. Denote E = U and E = D for the events uprighting and survival, respectively. Our full regression models for both first uprighting and survival are

$$\lambda_{Ei}(t) = \lambda_{E0}(t)\exp(S_i + \beta_1 T + \beta_2 A + \beta_3 M + \beta_4 A^2 + \beta_5 M^2 + \beta_{1,i} T + \beta_{2,i} A + \beta_{3,i} M + \beta_6 TA + \beta_7 TM + \beta_8 AM + \beta_9 TA^2 + \beta_{4,i} A^2 + \beta_{6,i} TA + \beta_{7,i} TM + \beta_{8,i} AM + \beta_{11} TAM + \beta_{11,i} TAM), \quad (1)$$

where: $\lambda_{Ei}(t)$ is the hazard function for event type E for the ith species at time t; $\lambda_{E0}(t)$ is the corresponding baseline hazard; $S_i, i = 1, 2$, are two fixed-effects parameters for identification of the three species (S_1 denotes *E. dilatata*, and S_2 denotes *Q. pustulosa*); T represents water temperature (°C) with coefficient β_1; A represents air shock temperature (°C), which we define as the difference between water and air emersion temperatures with coefficient β_2; M represents air exposure duration (min) with coefficient β_3; A^2 and M^2 are quadratic (∪ or ∩-shaped) effects of air shock and exposure duration, respectively; $\beta_{1,i}T$ represents the species × water temperature interaction; $\beta_{2,i}A$ represents the species × air shock interaction; $\beta_{3,i}M$ represents the species × air-exposure duration interaction; TA, TM, and AM are two-way interactions among T, A and M; TA^2 is the interaction between T, and the quadratic effect of A; $\beta_{4,i}A^2$ is the interaction between species and A; $\beta_{6,i}TA$, $\beta_{7,i}TM$, and $\beta_{8,i}AM$ represent three-way interactions among species, A, T, and M; TAM is the three-way interaction between T, A, and M; and $\beta_{11,i}TAM$ is the four-way interaction among species, T, A, and M. In this model, "interactions" are on the log scale. Although in such terminal events as death, it is customary to refer to $\lambda(t)$ as the hazard function for deleterious events such as death, the term intensity is more appropriate than hazard for events such as first uprighting. Therefore, we refer to $\lambda(t)$ as either the hazard or intensity function, depending on whether we are addressing survival or first uprighting, respectively. We fitted Eq. (1) to the uprighting and survival data by maximizing the partial likelihood (Cox 1972), and constructed likelihood-ratio and Wald chi-square tests for each parameter (Hosmer and Lemeshow 1999) with the SAS PHREG software (SAS Institute 1997). For each event type, we began with our full regression model [Eq. (1)] and, one-by-one, deleted terms for which the corresponding likelihood-ratio chi-square test was not significant at the $\alpha = 0.05$ level, except we did not delete terms for which a higher-order interaction was statistically significant. This model reduction process identifies the simplest model for each event type that preserves the hierarchical structure of Eq. (1). Our recorded event times were based on observations at fixed times rather than exact measurements of event times, and, therefore, contained ties. We used Efron's method to adjust for tied event times, which has been shown to perform better than alternatives (Hertz-Picciotto and Rockhill 1997). We assumed that events occurred at the observation time rather than, for example, the temporal midpoint between successive observations to produce conservative estimates of the intensity of first uprighting or the hazard of mortality.

A particularly desirable feature of proportional hazard regression models is that the parameters have natural interpretations that provide informative descriptions of the event times. Because these models are still unfamiliar in ecology, interpretation requires some explanation. The hazard function $\lambda(t)$ quantifies the number of events per interval of time at time t. From Eq. (1), the dimensionless hazard ratio (risk ratio) at time t is given by $HR(t) = \lambda_i(t)/\lambda_0(t) = \exp[S_i + \cdots + \beta_{11,i}TAM]$. For such categorical variables as species S_i in our analysis, the hazard ratio for species i relative to the baseline species is $\exp(S_i)$, and the hazard ratio for species 1 relative to species 2 is $\exp[S_1 - S_2]$ in the absence of higher-order interactions. If, for example, $\exp(S_i) = 0.5$, we say that the *relative* hazard (or intensity) for species i is only 50% of that for the baseline species. For continuous covariates such as water temperature, the statistic $100[\exp(\beta_1) - 1]$ is the estimated percentage change in the hazard (or intensity) ratio for each unit change in temperature. If, for mortality, $\beta_1 = 0.5$, then the hazard ratio increases by approximately 65% for each 1 °C increase in temperature (Allison 1995). These interpretations extend to more com-

TABLE 1.

Physical characteristics of three mussel species after aerial exposure at various water–air temperature differentials.

Water Temperature (°C)	Species	Mean Length (mm)	Wet Weight (g)
25	*Elliptio dilatata*	80.57 (9.7)	53.79 (18.4)
	Quadrula pustulosa	61.82 (13.2)	78.27 (42.0)
	Lampsilis cardium	100.32 (10.7)	185.59 (54.0)
10	*E. dilatata*	78.64 (10.4)	52.21 (19.6)
	L. cardium	99.71 (11.6)	179.74 (33.1)

Numbers in parentheses are the standard deviation of the mean.

TABLE 2.

Proportional hazards (intensity) model fitted to the time to first uprighting for *Elliptio dilatata*, *Quadrula pustulosa*, and *Lampsilis cardium*. *Lampsilis cardium* at 0 °C constitute baseline conditions.

Parameter (Effect)	Estimate (SE)	Wald χ^2	*P*-Value
S_1 (species: *E. dilatata*)	0.3142 (0.1965)	2.6	0.11
S_2 (species: *Q. pustulosa*)	− 0.3031 (0.0821)	13.6	< 0.01
β_1 (water temperature T)	0.1491 (0.0083)	319.0	< 0.01
β_2 (air shock A)	− 0.0677 (0.0146)	31.4	< 0.01
β_4 (A^2)	0.0055 (0.0011)	26.9	< 0.01
$\beta_{1,1}$ ($S_1 \times T$)	− 0.0562 (0.0096)	34.1	< 0.01
β_6 ($T \times A$)	0.0027 (0.0007)	16.2	< 0.01
β_9 ($T \times A^2$)	− 0.0003 (0.0001)	30.9	< 0.01

See text for explanation of the model and parameters.

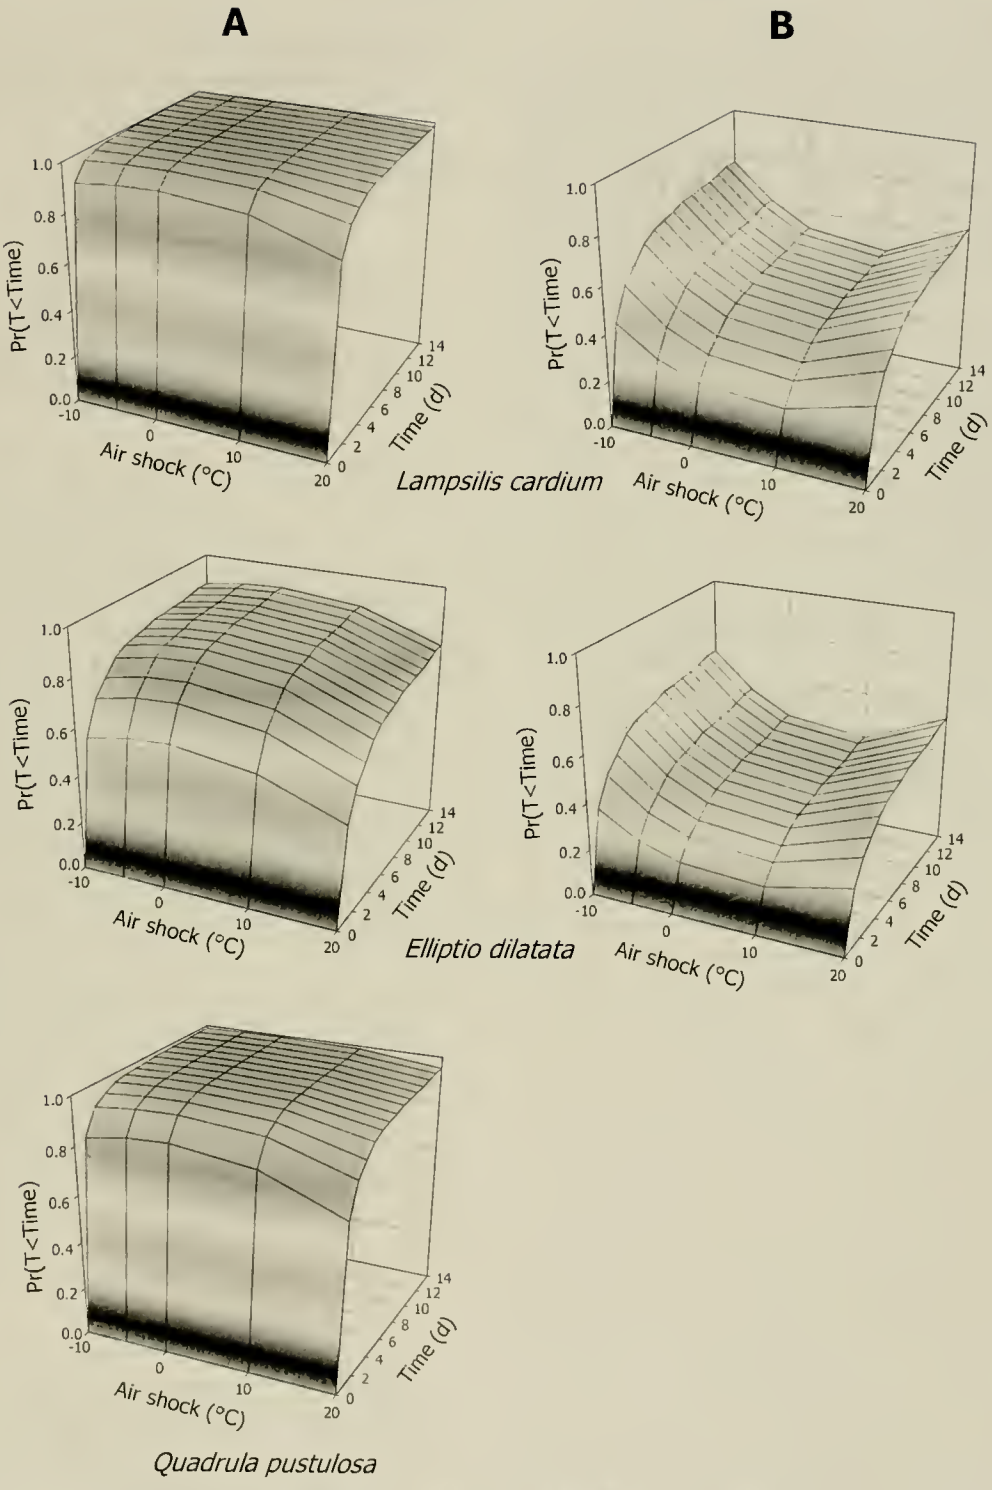

Figure 2. Estimated probabilities of times to first uprighting, T, were less than times on the axis marked Time for *L. cardium*, *E. dilatata*, and *Q. pustulosa* at five air shock temperatures obtained from proportional hazards model (Table 2). Air shock was defined as the difference between water and air emersion temperatures. Letters A and B refer to the 25 and 10 °C water exposure treatments, respectively.

plicated models having significant interactions. For example, from Eq. (1) the hazard ratio for species 1 to species 2 at water temperature T, air shock temperature A, and exposure duration M is given by $\exp[S_1 - S_2 + (\beta_{1,1} - \beta_{1,2})T + (\beta_{2,1} - \beta_{2,2})A + (\beta_{3,1} - \beta_{3,2})M + (\beta_{4,1} - \beta_{4,2})A^2 + (\beta_{6,1} - \beta_{6,2})TA + (\beta_{7,1} - \beta_{7,2})TM + (\beta_{8,1} - \beta_{8,2})AM + (\beta_{11,1} - \beta_{11,2})TAM]$.

Although hazard ratios have natural interpretations that provide the means to assess the relative importance of the explanatory variables, we display model features using graphs of the "survivor" functions (Hosmer and Lemeshow 1999), which are probabilities that times until events exceed some time t. We computed product-limit survival estimates (Kalbfleisch and Prentice 1980) of the

survivor function and used those to display model features for both first uprightings and deaths.

RESULTS

Physiochemical Characteristics of Water

Temperature, dissolved oxygen (Yellow Springs Instrument Model 58 oxygen meter), and pH (Beckman Model Φ11 meter) were measured daily in each tank during each test. Averages and standard deviations (SD, in parentheses) for physiochemical characteristics of water in all tanks at each water temperature (25 and 10 °C, respectively) were as follows: temperature 24.5 °C (0.8), 10.1 (0.4); dissolved oxygen 8.2 mg/L (0.4), 11.5 mg/L (0.6); pH 8.10 (0.06), 8.13 (0.09). Un-ionized ammonia concentrations (mg/L) were measured in six randomly selected tanks for each test (range, 0.0013 to 0.0054 mg/L), and were well below the concentrations reported to adversely affect mussel growth (0.036 mg/L at 6 weeks, Sparks and Sandusky 1981) or survival (96 h LC50 = 1.1 mg/L, Arthur et al. 1987). The mean relative humidity over all five tests during aerial exposures was 63.6 (2.19).

Mussel Characteristics

The average length and wet weight of mussels were similar within a species between water temperatures (Table 1). The sex ratios (male:female) of *E. dilatata* and *Q. pustulosa* in the 25 °C treatment were similar (66 male:67 female and 74 male:65 female, respectively); however, the sex ratio for *L. cardium* was approximately 2:1 males to females (209 male:111 female) in the 25 °C water treatment and approximately 3:1 males to females (239 male:80 male) in the 10 °C water treatment.

Uprighting Behavior

The intensity of first uprighting differed among species, water temperatures, and air shock temperatures in a complex way involving multiple interactions (Wald $\chi^2 = 633.2$, $df = 8$, $P < 0.01$). There was a significant interaction between *E. dilatata* versus the other species and water temperature ($P < 0.01$; Table 2). Both water temperature and air shock temperature were important predictors of times to first uprighting. As expected, the intensity of uprighting was greater at the higher water temperature. Moreover, the effects of air shock differed with water temperature and showed a significant quadratic response (∪ or ∩-shaped, Fig. 2). At the 10 °C water temperature, the uprighting response was ∪-shaped; whereas, at the 25 °C water temperature, the response was ∩-shaped. Although air exposure duration had no statistically significant effect, it is important to note that, by definition, any response to air shock temperature requires exposure. In this experiment, the briefest air shock duration was apparently sufficient to affect uprighting intensity, and longer durations showed no additional effect.

In addition to uprighting, we also observed other behavioral responses to emersion. Shell gaping behavior was observed in *L. cardium* during emersion in >25 °C air for 30 min and in *E. dilatata* during emersion in 45 °C air for 15 min. Also, the occurrence of foot extension increased with emersion time in *E. dilatata* at 45 °C (~70% at 15 min duration to ~100% in the 60-min exposure duration). All three species extruded mucus from the siphonal region after emersion in 45 °C air for 60 min.

Survival

Survival of mussels differed among species and with water temperature, air shock, and air exposure time in a complicated way involving both two- and three-way interactions (Wald $\chi^2 = 253.82$, $df = 14$, $P < 0.01$). Survival of *Q. pustulosa* did not differ significantly from *L. cardium*, the baseline species, at any water or air shock temperature, or with air exposure time (Table 3, Fig. 3). *Elliptio dilatata* differed significantly from *L. cardium* up through interactions with the linear and quadratic effect of air shock temperature, and the three-way interaction among species, water temperature, and air shock temperature (Table 3). The parameters (effects) for *E. dilatata* (S_1), air shock (A), squared air shock (A^2), and the *E. dilatata* × air shock ($S_1 \times A$), water temperature × air shock ($T \times A$), air shock × exposure duration ($A \times M$), *E. dilatata* × squared air shock ($S_1 \times A^2$), *E. dilatata* × water temperature × air shock ($S_1 \times T \times A$), and water temperature × air shock × exposure duration interactions ($T \times A \times M$) were significantly different from zero (Table 3). Through the last day of the experiment, survival varied only slightly except for the *E. dilatata* in the 25 °C water temperature treatment that were exposed to large positive air shocks (Fig. 3). For *E. dilatata* in the 25 °C water treatment, survival probabilities decreased significantly in the 60-min air exposure duration treatments (Fig. 4).

DISCUSSION

Over-all mussel survival after emersion was high (93%) and indicated that these mussel species are remarkably resistant to emersion and thermal shock. For example, in the 10 °C water tests, both *L. cardium* and *E. dilatata* survived the air shock treatments despite a 20 °C air–water differential and emersion in subzero air. However, variations in tolerances to water–air treatments were evident among species at the higher water temperature. *Elliptio dilatata* died within 24-h postemersion to the 45 °C air temperature treatment, with 100% mortality at the 60-min aerial exposure duration and 50% mortality at the 30-min duration. Surprisingly, the other two species survived the highest air shock treatment. Several studies have documented that mussel survival, during and after emersion, is directly related to relative humidity (Byrne and Mc-

See text for explanation of the model and parameters.

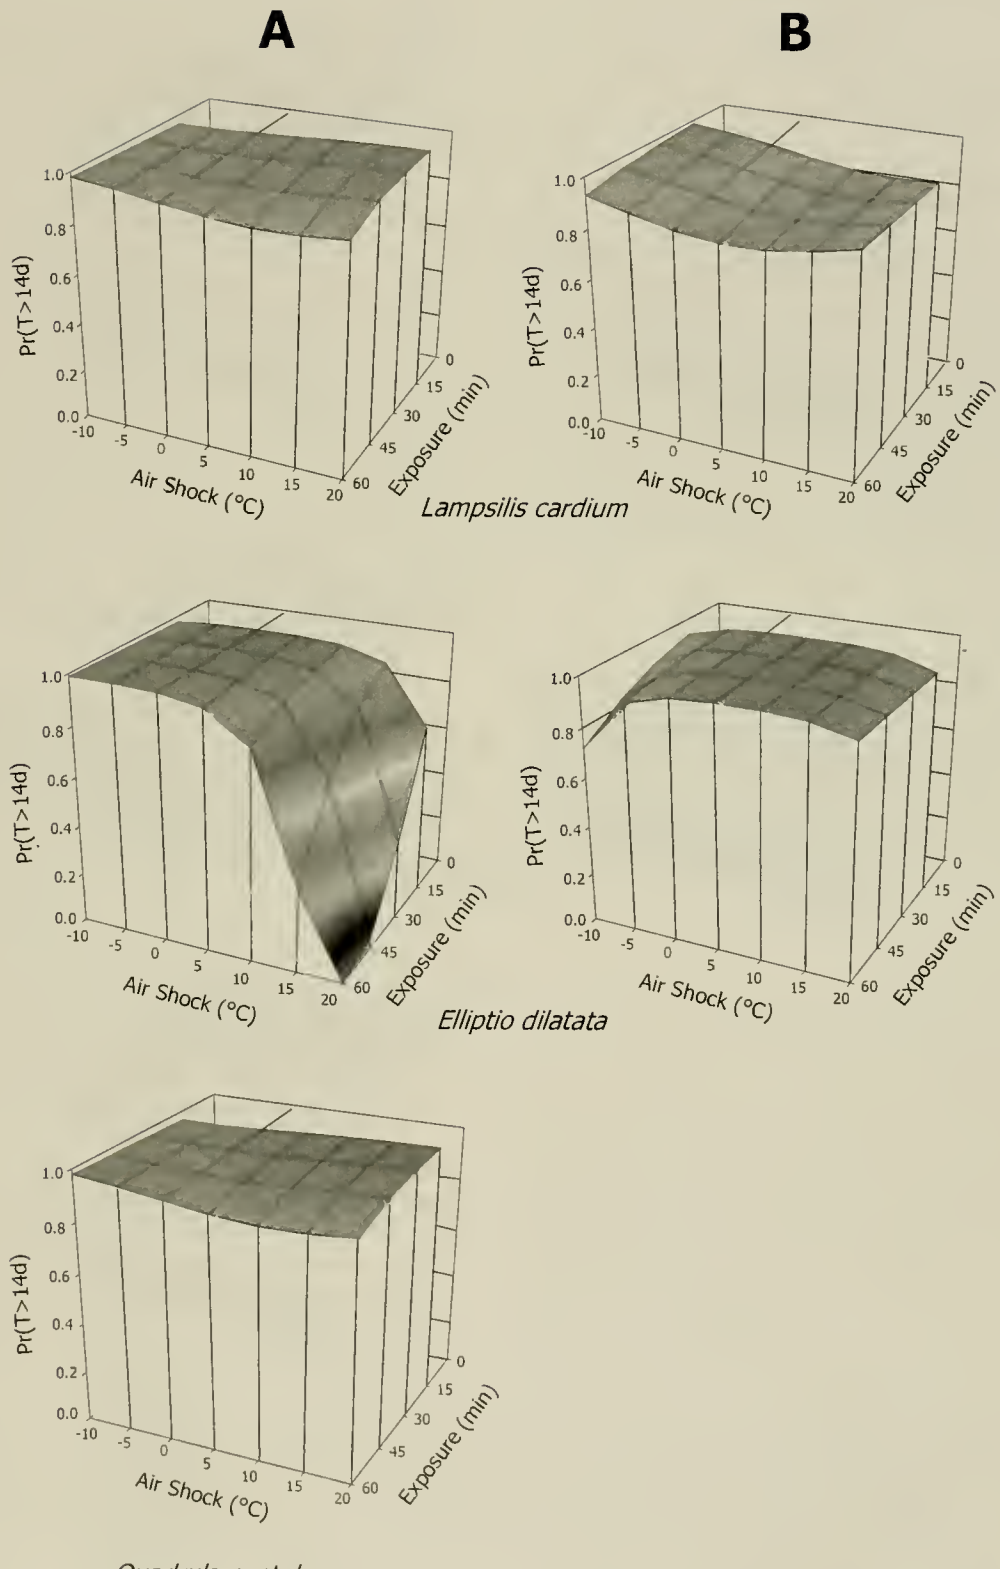

Figure 3. Estimated survival probabilities, T, were greater than times on the axis marked Time for *L. cardium*, *E. dilatata*, and *Q. pustulosa* at five air shock temperatures and three exposure durations obtained from proportional hazards model (Table 3). Air shock was defined as the difference between water and air emersion temperatures. Letters A and B refer to the 25 and 10 °C water exposure treatments, respectively.

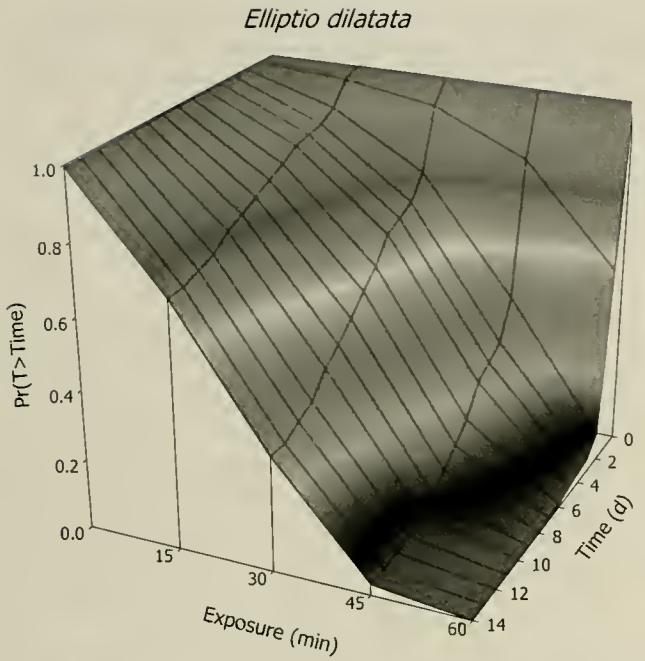

Figure 4. Estimated survival probabilities, T, were greater than time on the axis marked Time for *E. dilatata* at three exposure durations for the 25 °C water, 45 °C aerial emersion test obtained from proportional hazards model.

Mahon 1994, Dietz 1974, Holland 1991). Dietz (1974) reported that *Ligumia subrostrata* Say could survive >40 d in air, if water loss was retarded; however, survival was reduced to 6–10 d when mussels were exposed in air with a low relative humidity (45–55%) at 25 °C. Relative humidity was held constant (60 ± 5%) across all treatments in our study. Survival probabilities are expected to vary directly with relative humidity and should not be considered absolute.

Uprighting behavior was more sensitive to species and treatment effects than survival. *Lampsilis cardium* uprighted before *Q. pustulosa* (25 °C water test only) or *E. dilatata* (25 and 10 °C water tests) regardless of air shock exposure or duration. In addition, both *L. cardium* and *E. dilatata* required more time to upright when held at the cooler water temperature than those held at the warmer water temperature. Waller et al. (1999), similarly found that mussels displaced in cooler water temperatures (7 °C) required up to tenfold more time to upright than those displaced in higher water temperatures (21 °C). In addition, the uprighting intensity for *L. cardium* and *E. dilatata* in this study showed a significant quadratic response to air shock temperature (Fig. 2). This is particularly noteworthy, because at the lower water temperature (10 °C), air shocks that differed greatly from water temperatures in either direction seemed to stimulate uprighting; whereas, at the higher water temperatures (25 °C), large positive or negative air shocks tended to inhibit uprighting slightly.

In addition to the uprighting behavior, we made qualitative observations on other sublethal behavioral responses to emersion and thermal stress, which included shell gaping, foot extension, and mucus production. These behaviors were elicited during emersion in air >25 °C; whereas, mussels closed their valves in air temperatures between −10 to 20 °C. *Elliptio dilatata* exhibited all three responses (shell gaping, foot extension, and mucus production) at the higher air shock temperatures in contrast to partial responses (shell gaping and mucus production only) in both *L. cardium* and *Q. pustulosa*. There was an apparent correlation between the occurrence of these behaviors with survival. Byrne and McMahon (1994) reviewed emersion capacities of freshwater bivalves and found that dessication resistance was inversely related to the degree of mantle exposure behavior of a species. We suggest that these behavioral responses, along with uprighting, are valuable sublethal indicators of stress and could be further quantified.

Emersion tolerance in freshwater bivalves may also be affected by shell characteristics. For example, both *L. cardium* and *Q. pustulosa* are spherical in shape; whereas, *E. dilatata* is elliptical. A sphere has the largest volume per outside surface area of any geometrical configuration (Kreith 1973). Conversely, an ellipse has a larger surface area per volume, which may have allowed the *E. dilatata* to reach a higher internal temperature more quickly and for a longer duration than the two spherically shaped species. Other physical characteristics of the shell that may affect emersion tolerance are shell thickness and over-all shell size. Shell thickness was similar among the three species that we tested; *Q. pustulosa* had the thickest shell, followed by *E. dilatata* and *L. cardium*, which have comparable shell thickness. In general, we expect thick-shelled species, such as amblemines, to be most tolerant to emersion and thinner-shelled species, such as anodontines, to be least tolerant. In addition, smaller individuals of a given species will be more sensitive to emersion than larger individuals because of the larger surface area to volume ratio. The rank of the average size of mussels in this study was *E. dilatata* (smallest), *Q. pustulosa*, and *L. cardium* (largest). Thus, these additional physical factors, shell shape, thickness, and over-all size, may also explain the greater sensitivity of *E. dilatata* to emersion.

One of the primary objectives of this study was to establish temperature guidelines for collection and handling of two federally endangered species, *Q. fragosa* and *L. higginsi*. *Quadrula pustulosa* and *L. cardium* were chosen as potential surrogates, because they are congeners. *Elliptio dilatata* was chosen as a second congener of *Q. fragosa*, because it is also an amblemine, but was more abundant at the study site than *Q. pustulosa*. Surprisingly, *Q. pustulosa*, and *L. cardium*, although in different subfamilies, responded more similarly than *Q. pustulosa* and *E. dilatata*, the two amblemines. These results demonstrate the difficulties associated with the use of surrogates and extrapolation to other mussel species, particularly when there is no sound biological basis for their selection. Therefore, guidelines should err on the side of the most sensitive species for which data are available, because results are seldom validated with threatened and endangered species.

In conclusion, these data provide baseline information for developing management guidelines for handling the species tested. Generally, we found that these species were tolerant of emersion, but may experience mortality in extreme conditions. Our survival estimates are conservative, because they were derived from laboratory studies conducted under controlled conditions rather than under field conditions in which air temperature and relative humidity can vary significantly within several hours. In addition, the microclimate to which the mussels are exposed can be very different from measured air temperature and relative humidity. Mussel survival can be enhanced by conducting field work in moderate conditions (10 to 25 °C air temperature), protecting the mussels from extreme changes in air temperature, and covering them with damp cloths during emersion to maintain high relative humidity.

ACKNOWLEDGMENTS

This research was partially supported by the U.S. Fish and Wildlife Service, Twin Cities Field Office in Bloomington, Minnesota. We thank Jim Luoma, Ron Hayden, Dennis Wasley, Mark Hanson, and the staff of Ecological Specialists, Inc. for assistance in the field and laboratory during this study. We also thank Chuck Kjos and Bob Hay for assistance with the planning and execution of this project.

ELEMENTAL SULFUR IN THE GILLS OF THE MANGROVE MUD CLAM *ANODONTIA EDENTULA* (FAMILY LUCINIDAE)

JUNEMIE HAZEL L. LEBATA
Aquaculture Department
Southeast Asian Fisheries Development Center
P.O. Box 256
Iloilo City 5000
Philippines

ABSTRACT Different sizes of the mangrove mud clam *Anodontia edentula* were collected from the mangroves in Bgy. San Roque in Estancia, Iloilo, central Philippines, and the mantle, gill, and foot tissues were analyzed for elemental sulfur content. Mangrove mud (substrate) was also analyzed for total sulfur content to establish the possibility of clam–bacteria symbiosis in this lucinid clam. Sulfur analysis showed highly significant ($P < 0.0001$) amounts of elemental sulfur in the gills (247.64 ± 63.28 μmoles/g FW) compared with the quantities observed in the mantle (0.84 ± 0.22 μmoles/g FW). Elemental sulfur was absent from the foot tissues. Results also showed a significantly ($P < 0.05$) decreasing elemental sulfur from the newly collected clams (mean = 461.18 μmoles/g FW) compared to those reared in the laboratory (mean = 159.08 μmoles/g FW: with mangrove mud substrate; mean = 45.18 μmoles/g FW without substrate), which were analyzed weekly until week 3, indicating that stored elemental sulfur is being utilized by the bacteria in the absence of sulfide. Total sulfur content of mangrove mud *in situ* was higher than that used as substrate in the experiment; where there were no significant differences from initial to final readings. This shows that mangrove mud *in situ* is linked to a steady sulfur source.

KEY WORDS: *Anodontia edentula*, lucinid, gills, elemental sulfur

INTRODUCTION

The mangrove mud clam *Anodontia edentula* (Linné, 1758) is widely distributed in the Indo-West Pacific region (Poutiers 1998). In the Philippines, it is one of the popular bivalves harvested from sandy–muddy bottoms near mangrove areas (Poutiers 1998, Sotto and von Cosel 1982). It is one of the most noteworthy species and a highly prized delicacy in the coastal areas where it is abundant; hence, an important source of food and livelihood. It grows to a maximum size of 8–9 cm shell length (SL), total weight of 180–210 g and is a potential aquaculture species.

A. edentula belongs to order Veneroida, family Lucinidae (Poutiers 1998), together with most eulamellibranchs containing symbiotic bacteria (Schweimanns and Felbeck 1985).

Animal–bacteria symbioses in marine mollusks have been observed in hydrogen sulfide-rich habitats, such as anoxic basins, sewage outfalls (Felbeck et al. 1981), seagrass beds (Cavanaugh 1983), mangrove swamps (Frenkiel et al. 1996, Vetter 1985), and in organically rich sediments (Janssen 1992).

The presence of elemental sulfur in the gills of some clams as energy source for clam–bacteria symbiosis has been reported by Vetter (1985) for *Lucinoma annulata, Calyptogena elongata*, and *Lucina floridana* and Dando et al. (1985) for *Myrtea spinifera*. In a review of Somero et al. (1989), the gills of the bivalve *Calyptogena ponderosa* have the highest elemental sulfur content (2593.8 μmole/g); whereas, *Solemya reidi* gills have the lowest (15.8 μmole/g).

Symbiotic bacteria in Philippine bivalves were first discussed by Janssen (1992) after his observation of bacteria in the gills of *Codakia tigerina* and *A. edentula* (using light microscopy), and *Fimbria fimbriata* (using transmission electron microscopy). In the present study, the observation of deep brown to deep purple, thick and fleshy gills having a single demibranch on each side of the gonad of *A. edentula* agrees with the description of Allen (1958) for several genera of lucinids, Dando et al. (1985) for *M. spinifera* and Distel and Felbeck (1987) for *L. aequizonata, L. annulata* and *L. floridana*, all of which are known for endosymbionts. These typical characteristics of lucinid gills possessed by *A. edentula* may support the claims of Janssen (1992).

To support further the evidences mentioned above, this study aimed to establish sulfur-oxidizing metabolism in *A. edentula* by analyzing elemental sulfur content of its mantle, gill, and foot tissues.

MATERIALS AND METHODS

Collection of Samples

A. edentula specimens were obtained from a narrow band (10–15 m) of 15–20 ha mangrove area in Bgy. San Roque, Estancia, Iloilo in central Philippines (11°14′N, 123°8′E) (Fig. 1). The trees are mostly secondary growths of *Sonneratia* and *Avicennia* spp. During low tide of spring tide periods, a very wide tidal flat is exposed, reaching 200–250 m seaward from the mangrove forest. There is no freshwater input in the study area.

Clams were collected during the ebb of a spring tide at daytime with the help of a clam collector who can recognize the opening of the clams' anterior inhalant tube on the surface of the mud. A specialized gear made of flattened iron bar attached to a wooden handle was used in digging the substrate. With this, the tube that led to the clam was carefully traced. Depth of each clam from the surface was measured during collection.

Physicochemical parameters were monitored during clam collection. Temperature was measured with a mercury thermometer; salinity with an Atago refractometer; pH with WTW pH 192 meter; and dissolved oxygen with a YSI Model 51B DO meter. Total sulfur, water, and organic matter content of the sediment were determined as prescribed by Beaton et al. (1968) and Dando et al. (1985).

Analyses of Sulfur Content

The presence of elemental sulfur in the tissues of *A. edentula* was examined, because elemental sulfur is the by-product of sulfide oxidation carried out by symbiotic bacteria (Atlas 1995) and is stored in the periplasmic space (Vetter 1985). Total sulfur in the

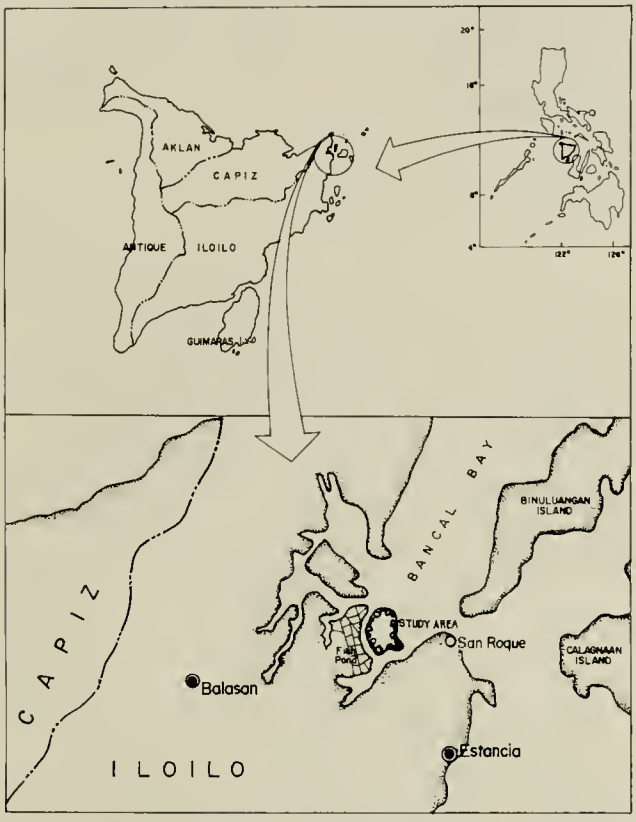

Figure 1. Map of Bgy. San Roque, Estancia, Iloilo in central Philippines showing location of collection site of *Anodontia edentula*.

substrate was measured both *in situ* and during laboratory experiments (weeks 1, 2, and 3) to know the levels in the clam's natural environment and the changes under laboratory conditions.

Elemental sulfur content of the tissues (mantle, gill, and foot) and total sulfur content of the substrate were determined initially (from newly collected samples) and through time (1–3 weeks) from laboratory-reared clams.

Clams and mangrove mud were collected from the study site and transported to the laboratory of the Aquaculture Department of Southeast Asian Fisheries Development Center (SEAFDEC/AQD) in Tigbauan, Iloilo. Upon arrival, all clams were measured (shell length, SL; shell width, SW; shell height, SH) using a caliper, weighed (total weight, TW) using a Mettler AE163 analytical balance, and numbered individually.

Elemental Sulfur Analysis

Six clams were randomly selected and dissected for their mantle, gills, and foot. Gill color of each clam was noted and described (Vetter 1985), and total wet weight and individual weights of each tissue were measured using a Mettler AE163 analytical balance. Tissues were then dried to constant weight in an oven at 60 °C, then pulverized by mortar and pestle. Elemental sulfur was extracted from the dried tissues using acetone and precipitated with barium sulfate seed suspension. Acidity of the medium (for sulfur extraction) was maintained by the addition of barium chloride (Beaton et al. 1968). Extracts were then subjected to turbidimetry. Absorbance was measured in a Shimadzu UV-1601 spectrophotometer at 440 nm wavelength. Elemental sulfur was computed and expressed as μmoles per g fresh weight (μmoles/g FW).

For comparison purposes, mantle, gill, and foot tissues of newly collected *Anadara antiquata*—another mangrove-associated bivalve inhabiting the same habitat as *A. edentula*—were also analyzed for elemental sulfur.

Two treatments (with and without mud substrate) replicated three times were prepared for sulfur analyses (elemental for the tissues and total for the substrate) through time. For the treatment with mud, three glass aquaria (0.75 × 0.44 × 0.42 m) were provided with 0.15 m newly collected mangrove mud to provide a substrate close to that found in their natural environment (Distel and Felbeck 1987, Vetter 1985), 100-L seawater (salinity conditions the same as in the field, 33–35 ppt), air stones, and 2-mm mesh black net cover. For the other treatment, the same were provided, except mud. Eight randomly selected clams were stocked in each aquarium. Sampling was done weekly for 3 consecutive weeks starting 1 week after the initial analysis. (The experiment could not be extended for a longer time, because 3 weeks is the maximum period the clams can survive in seawater without substrate.) Two clams were randomly chosen from each aquarium and processed as in the initial analysis. Gill coloration was scored (very light brown = 2; light brown = 4; brown = 6; dark brown = 8; and blackish brown = 10) and correlated with its elemental sulfur content.

Temperature, salinity, pH, dissolved oxygen, water and organic matter content, and total sulfur content of the mud were taken during the initial and the weekly samplings.

Total Sulfur Analysis

For the total sulfur content analysis, sediment samples were air dried and ashed in an Automatic Muffle Furnace MFD-200N at 700 °C for 40 min. Total sulfur was extracted using hydrochloric acid, processed as in elemental sulfur and the absorbance measured at 440 nm (Beaton et al. 1968). Total sulfur was expressed in percentage. All analyses were conducted at the Centralized Analytical Laboratory of SEAFDEC/AQD. Elemental sulfur contents were compared: (1) among tissues; (2) with time; and (3) between treatments (with or without mud substrate). Analysis of variance (ANOVA) was used to determine significant differences between means of elemental sulfur content of tissues at different times and treatments ($\alpha = 0.05$) (SAS 1988) and Duncan's Multiple Range Test (DMRT) to isolate these differences (Gomez and Gomez 1984). Weekly means of sulfur content of clams reared with and without mud substrate were compared using *t*-test (SAS 1988). "Clams" in the text refer to *A. edentula*, unless otherwise stated as *A. antiquata*.

RESULTS

During sample collection, substrate temperature ranged from 27.0–30.0 °C (mean = 28.70); salinity 33.0–36.0 ppt (mean = 35.0); pH 5.15–6.55 (mean = 5.63); D.O. 0.2–1.0 ppm (mean = 0.38); water content 49.4–56.0% (mean = 53.4); organic matter 5.08–6.58% (mean = 6.24); and total sulfur content 1.3–2.2% (mean = 1.8). There was no rainfall during the entire collection period.

A. edentula were collected at depths ranging from 0.28–0.50 m from the surface. Its foot was observed to extend several times longer than the clam's shell length. On the other hand, *A. antiquata*, which were analyzed for comparison purposes, thrive at

shallower depths (surface–0.1 m). Its foot was hatchet-like and does not extend longer like the foot of *A. edentula*.

During laboratory culture of the clams, water temperature ranged from 27.0–28.5 °C (mean = 27.9); salinity 33.0–35.0 ppt (mean = 34.0); pH 7.6–8.3 (mean = 8.05); and D.O. 3.4–6.0 ppm (mean = 4.41). Total sulfur content of the substrate ranged from 0.3–0.7% (mean = 0.4); water content 49.0–66.8% (mean = 58.18), and organic matter content 5.15–6.58% (mean = 5.72).

The organic matter content of the newly collected substrate (6.24 ± 0.29%) was not significantly different from those stocked with clams (5.72 ± 0.57%) for 3 weeks. However, sulfur content of mangrove mud *in situ* was higher (1.8 ± 0.15%) than the one used as substrate in the experiment (0.4 ± 0.1%); the latter had no significant difference from initial to final readings.

In newly collected clams, the gills were deep brown to deep purple, thick and fleshy, as compared with the gills of individuals kept for 3 weeks in the aquaria, which were thin and filamentous. In the course of the 3-week sampling period, there was a slight fading of color in the gills. Correlation analysis showed no relationship between gill coloration and elemental sulfur content. However, gills of newly collected *A. antiquata* were reddish brown, thin, and filamentous.

There was not much change in the total wet weight of the clams. Newly collected clams were slightly lighter (36.01 ± 2.06 g) compared with clams weighed weeks later (36.84 ± 2.05 g) during laboratory experiment.

Elemental sulfur levels were significantly different (ANOVA, $P < 0.0001$) in the gills (247.64 ± 63.28 μmoles/g FW) compared with the mantle (0.84 ± 0.22 μmoles/g FW). Elemental sulfur was absent from the foot tissues (Fig. 2). Results also showed a significant decrease (ANOVA, $P < 0.01$) in elemental sulfur between the newly collected clams and those stocked in aquaria (both in mud and without mud substrate) and analyzed 1–3 weeks later (Fig 3a). Minimal sulfur was detected in the mantle only at the start of the experiment (Fig. 3b).

Results further showed that elemental sulfur in the gills of clams stocked in mud substrate were significantly higher than those stocked in seawater only for weeks 1 (*t*-test, $P < 0.05$) and 2 (*t*-test, $P < 0.05$). However, there was no significant difference between these two treatments in week 3 (Fig. 4). For the mantle, there was no significant difference between treatments. No elemental sulfur was detected in the mantle, gill, and foot tissues of *A. antiquata* (data not shown).

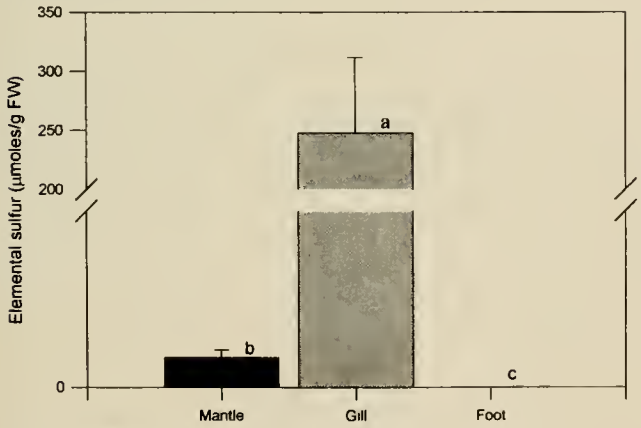

Figure 2. Means ± SE of elemental sulfur content of different tissues of *Anodontia edentula* (ANOVA, $P < 0.0001$).

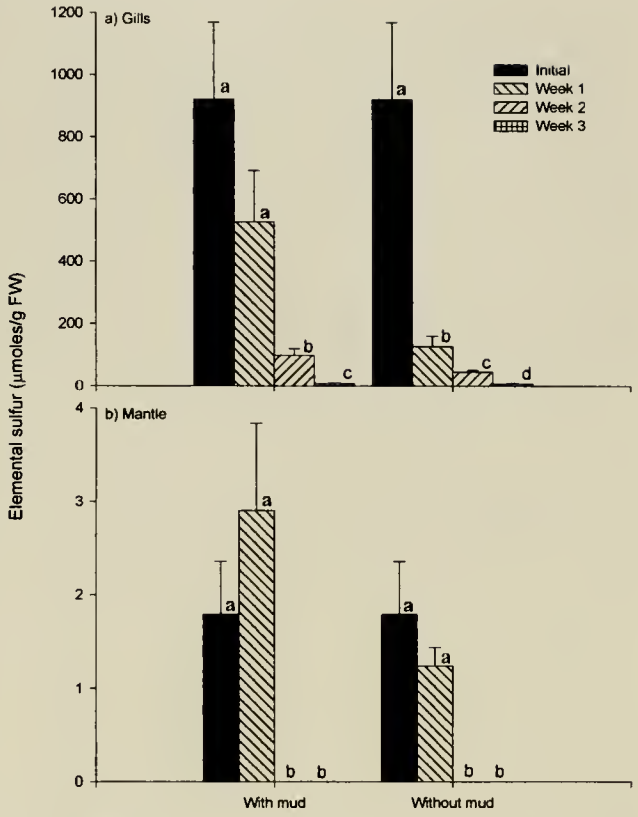

Figure 3. Means ± SE of elemental sulfur content of *Anodontia edentula* a) gills and b) mantle from initial to week 3 readings in clams stocked in mangrove mud substrate and in seawater only. Means with the same superscript are not significant. (ANOVA, $\alpha = 0.05$)

DISCUSSION AND CONCLUSION

The major natural sources of sulfur in the soil are organic matter and soil minerals. Most of these are bound, but over time, microorganisms can simplify them into soluble inorganic forms (Brady 1990). Hydrogen sulfide and other sulfides are produced during mineralization of organic sulfur (proteins and other organic combinations) under anaerobic conditions (Atlas 1995, Brady

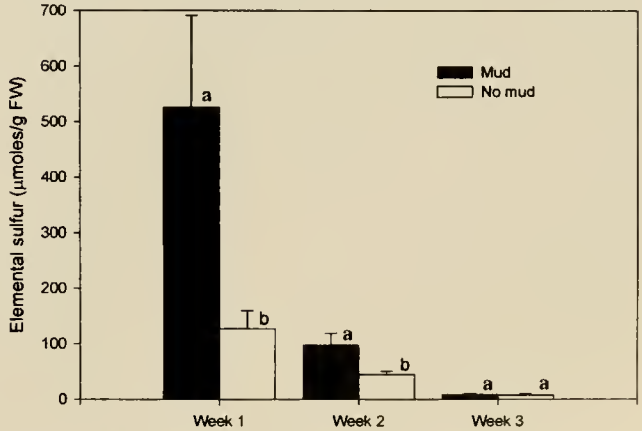

Figure 4. Means ± SE of elemental sulfur content of *Anodontia edentula* gills between treatments from week 1 (*t*-test, $P < 0.05$), week 2 (*t*-test, $P < 0.05$) week 3 (*t*-test, $P > 0.05$). Means with the same superscripts are not significant.

1990). These sulfide ions will undergo hydrolysis to form gaseous H_2S causing the rotten egg smell of swampy or marshy areas (Brady 1990) including mangroves where *A. edentula* thrives.

In a clam–bacteria symbiotic relationship, the clam's anatomy and its location in the substrate/mud play very vital roles. According to Distel and Felbeck (1987), clams should be strategically situated in an interface between a sulfide-generating zone (anoxic) and water with sufficient oxygen (oxic). The foot of *A. edentula*, which can extend up to several times longer than its length, gives it the capacity to construct a ventilation burrow (Reid and Brand 1986) and allows it to draw water from the surface (Dando et al. 1985). The tip of the foot is specialized for the construction of this inhalant tube. It is provided for with glands that lay down mucus for the building of the tube (Allen 1958). The clam gains access to oxygenated water through this inhalant tube. Its location (0.28–0.50 m deep in mangrove mud) may allow it direct access to sulfide. In cases where sulfide is limiting, Childress et al. (1991) have proved that the foot can dig deeper and is responsible for the uptake of sulfide from deeper parts of the substrate. Sulfide is taken up across the foot of the clam and into the blood that transports it to the gills for use of the bacterial symbiont (Ruppert and Barnes 1994).

Sulfide is a highly reduced energy molecule and a variety of biological systems have evolved to oxidize sulfide in orderly enzyme-regulated steps to harness the energy and avoid poisoning (Bagarinao 1992). In a clam–bacteria symbiosis, bacteria are assumed to provide the mollusk with chemosynthetically fixed carbon dioxide via aerobic oxidation of sulfide (Vetter 1985). Oxidation of sulfides and other reduced sulfur compounds provides energy to the bacteria to fix carbon dioxide into organic compounds that become available to the host clam (Distel and Felbeck 1987, Kelly and Harrison 1989). The Calvin cycle is the main metabolic pathway used by the bacteria to convert carbon dioxide to organic carbohydrates powered by the energy (ATP) generated from the oxidation of sulfides (Atlas 1995). In the process of oxidation, sulfide is converted into elemental sulfur and stored for future use (Childress and Mickel 1982, Vetter 1985). Using EDX microanalysis, Reid and Brand (1986) found sulfur as the dominant elemental inclusion of bacteria in a lucinid clam *Parvilucina tenuisculpta*.

In this study, elemental sulfur was present in highly significant amounts in the gills (max: 1907.20 μmoles/g FW from a newly collected clam; min: 1.38 μmoles/g FW from a clam reared without substrate and analyzed at week 3) (Fig 3) and based on the compilation of Somero et al. (1989), these values are within the range of elemental sulfur content (0.22–2593.8 μmoles/g FW) for different species of bivalves containing symbiotic bacteria. The very wide difference between the maximum and minimum values may be attributable to the mobilization of elemental sulfur by the bacteria in the absence of external sulfide (Vetter 1985) in aquaria not provided with mud substrate. This is clearly exhibited by the significant decrease in elemental sulfur content of the gills from the initial sampling to week 3 (Figs. 3a, 4). The initial samples showed to have significantly higher elemental sulfur content than those stocked in mud and those in seawater (Fig. 3a). Furthermore, clams stocked in mud have significantly higher sulfur content at weeks 1 and 2 than those stocked in seawater only. However, at week 3, there was no significant difference between the two treatments. In the first 2 weeks, bacteria in clams maintained in mud may have utilized all available sulfide in the mud; whereas, those stocked in seawater only may have depended on their elemental sulfur reserves. Moreover, around week 3, the clams stocked in mud may have also utilized their sulfur reserves because of inadequate sulfide supply in the mud. In the absence of external sulfide, elemental sulfur represents a novel inorganic energy reserve for the animal–bacterial symbiosis (Vetter 1985), which, according to Powell and Somero (1985), is the most reduced nontoxic inorganic form of sulfur.

If sulfur globules are confined in the periplasmic space of bacteria (Vetter 1985) then *A. edentula* must have these endosymbiotic bacteria in their gills to store sulfur.

The presence of elemental sulfur in very minimal amounts in the mantle may be attributable to the connection that links the mantle and the gill, which may have served as a passage to some bacteria containing elemental sulfur globules. There is an insertion and fusion of the posterodorsal margins of the gills with the muscular posterior mantle edge (Reid and Brand 1986). However, this may also be attributable to contamination during dissection.

The deep brown to deep purple, thick and fleshy gills of *A. edentula* were also observed by Felbeck et al. (1981) in bivalves collected from sulfide-rich habitats containing sulfide oxidation enzymes in contrast with the small, light-colored gills of those lacking these enzymes. According to Distel and Felbeck (1987), the dark coloration and thickness of the gills are attributable to the presence of a thick layer of subfilamentar tissue perforated by regular arrays of bacteriocyte channels formed by bacteriocyte cylinders containing the bacterial symbionts.

The very slight, nonsignificant increase in wet weight of cultured clams (3 weeks) compared to the newly collected ones used for the initial analysis may be caused by the water trapped inside the clams' body cavity. Newly collected clams were not weighed immediately in the field but were transported to the laboratory and weighed 8 h after collection. Water trapped inside the body cavity was exuded. During laboratory experiment, clams were weighed immediately upon harvest and so water trapped inside the body cavity was released only during dissection and has, therefore, added to the weight of the individual.

The absence of elemental sulfur in *A. antiquata* simply shows that only lucinid clams harboring endosymbiontic bacteria in their gills are capable of sulfur-oxidizing metabolism and have the capacity to store these sulfur globules.

The results of the experiment, therefore, support the presence of endosymbiotic bacteria in *A. edentula* as exhibited by the presence in significantly higher amounts of elemental sulfur in the gills.

ACKNOWLEDGMENT

EVALUATION OF TAG TYPES AND ADHESIVES FOR MARKING FRESHWATER MUSSELS (MOLLUSCA: UNIONIDAE)

DAVID P. LEMARIÉ, DAVID R. SMITH, RITA F. VILLELLA, AND DAVID A. WELLER

U.S. Geological Survey,
Biological Resources Division,
Leetown Science Center,
Aquatic Ecology Laboratory,
Kearneysville, WV 25430

ABSTRACT Prior to initiating a long-term tagging program on freshwater mussels, we evaluated three varieties of tags (Northwest Marine Technology Visual Implant Tag, Floy Fingerling Tag, and Hallprint Shellfish Tag) two types of adhesives (3M two-part epoxy and Krazy Glue cyanoacrylate), and four bonding times before immersion in water (2, 5, 10, and 15 min). Tags were applied to empty shells for two phases of testing. First, legibility was visually scored for each of the immersion times. The two-part epoxy became cloudy at immersion times < 15 min, was easily abraded after curing, and was, therefore, eliminated from further testing. The visual implant tag also was eliminated from further testing because the printing dissolved in the cyanoacrylate. In the second phase, the fingerling tag and the shellfish tag bonded with cyanoacrylate were tested for durability and retention under natural conditions in a shallow stream and under highly abrasive conditions in a standard gem tumbler containing coarse metal shavings. Tag losses after 16 wk in the instream test were 5.3% for the shellfish tag and 2.6% for the fingerling tag. These tests revealed no loss of legibility after the removal of material that accumulated on the tag surface. There was no appreciable wear of either tag type after 1 wk in the gem tumbler. Flexible polyethylene shellfish tags were chosen for field application because they are thinner and available with a larger number of individual codes than fingerling tags. Tags bonded to the shells of live mussels with cyanoacrylate can be immersed in water in as little as 2 min after application without affecting retention. This method was used to double-tag 1,372 mussels at a monitoring site on the Cacapon River in West Virginia. After 2 y, the total tag loss in 325 recovered mussels was 0.46%.

KEY WORDS: Freshwater mussels, tag, adhesive, tag retention

INTRODUCTION

External identification of individual freshwater mussels is highly desirable for tracking passive and active movements, growth analyses, population studies, and laboratory experiments. The marking of freshwater mussels is particularly problematic because these are long-lived species, and programs to collect population information could potentially last for many years, requiring excellent long-term legibility and retention. Additionally, marks on freshwater mussels are subjected to abrasion from animal movement through mineral substratum and water-borne materials in fast-flowing water. Any marking method must have minimal effects on the survival, growth, and behavior of the tagged animal. The ideal marks should be easy to apply, inexpensive, and readily available, especially when needed for large-scale marking programs. In addition to high legibility, the tags should be small and of subdued colors to avoid the potential for increased susceptibility to predation in field studies (although bright colors for easy visibility in laboratory studies may be desirable) and should be commercially available with a large number of codes.

Freshwater mussels have been individually marked by scratching numerals (Isley 1914, Couilliard et al. 1995), drilling codes in the periostracum (Thoma et al. 1959), attaching pendant tags with wire passed through a hole in the shell (Isley 1914), and attaching plastic labels with adhesive (Neves and Moyer 1988). Sequentially numbered plastic tags have been obtained from commercial vendors (Neves and Moyer 1988) or created with Dymo label makers (Balfour and Smock 1995). Adhesives used for plastic tags include dental cement (Downing and Downing 1993), wet surface repair putty (Balfour and Smock 1995), and cyanoacrylate (Neves and Moyer 1988). Cyanoacrylate also has been widely used to attach plastic tags to a variety of marine shellfish, including abalone (McShane 1989), scallops (Heald 1978, Williams and Dredge 1981, Gwyther 1989), and limpets (Treble et al. 1993). Neves and Moyer (1988) used this combination for freshwater mussels and found no apparent effects on growth or survival up to 4 y later. While long-term tag retention and legibility have been documented for freshwater mussels, they have not been quantitatively evaluated.

Because we desired to establish retention and legibility information before initiating long-term tagging programs, we conducted several short-term tests to select tags and adhesives. We elected not to scratch codes into the periostracum for fear that this action could cause increased shell erosion and the high-contrast marks could make the animals more visible to predators. Two-year retention and legibility results from a field monitoring study, initiated during the summer of 1996, also are presented here.

MATERIALS AND METHODS

The fingerling tag and the visible implant tag (so named for its intended use in clear tissue on fish) were initially selected and were used in adhesive immersion and legibility tests (Table 1). Shellfish tags were acquired after the adhesive tests were complete and were used in all subsequent evaluations. Shellfish tags are similar in size to the fingerling tags but are significantly thinner and carry larger characters and a greater number of characters. Both the fingerling tag and shellfish tag were previously used for marking freshwater mussels (R. Neves pers. comm.).

We selected adhesives that were readily available at reasonable cost, easily dispensed, fast curing, and known to be durable while immersed in water. A fast-curing adhesive was particularly desirable to minimize emersion time, thus reducing stress to the mussels

and providing a more efficient tagging process. Because tags will be exposed to highly abrasive conditions as animals move through the mineral substrate, our initial assumption was that it would be necessary to cover the tags with clear adhesive to protect the printed codes, especially in the case of the visible implant tags, which are very small and delicate. A two-part epoxy (DP-100, 3M, St. Paul, MN) and a cyanoacrylate (Krazy Glue, Borden, Inc., Columbus, OH) fit all of these considerations, and were selected for the initial round of tests.

The tag and adhesive combinations were tested in a two-phase process. First, we tested the ability of the adhesive to form a secure bond and to remain clear when immersed in fresh water shortly after application. Second, we evaluated the durability of the selected adhesive and tag types when exposed to natural stream conditions and a highly abrasive environment. Tags were applied to empty shells collected from local streams. To prevent exfoliation of the periostracum due to drying, all shells were stored in water before and after tagging. Unsatisfactory adhesives and tags were eliminated at each step. The tag and adhesive combination that was found to perform best in these initial tests then was used to double-tag live mussels for monitoring in a multiyear field study. Double-tagging assumes that both tags are retained independently and can be used to estimate tag loss (Arnason and Mills 1981).

Evaluation of Adhesives

Adhesives were evaluated initially by attaching tags to the exterior surfaces of empty shells and allowing them to air dry for 2, 5, 10, and 15 min prior to immersion in water. A maximum duration of 15 min was chosen to minimize the potential stress to live animals and to maintain efficient tagging rates in field applications. Ten replicates of each treatment (tag type, adhesive, time to immersion) were prepared. All tags were completely covered with the adhesive. Tagged shells were stored in 1-L containers filled with spring water. Weekly observations were conducted through 4 wk to evaluate legibility and the retention of the tags. Shells were removed from the water to conduct the observations, then immediately were replaced. Legibility was scored by a single observer (DPL) as easy to read (i.e., it could be read immediately), difficult to read (i.e., it required close scrutiny or scraping of encrusting glue), barely legible (i.e., despite the aforementioned efforts, an 'educated guess' was still necessary to make out the numbers), or illegible. Numeric scores of 3 through 0 were used to calculate mean legibility scores for each treatment.

Evaluation of Tags

Based on the results of the initial tests, only cyanoacrylate was used for further testing. In addition, due to legibility problems to be discussed later, the visible implant tags were replaced with shellfish tags for subsequent evaluations (Table 1).

Instream Immersion Test

As in the adhesive test, shells were immersed 2, 5, 10, and 15 min after the application of tags. After remaining in water for 1 wk, one shell from each treatment was imbedded in a natural position in a block of concrete. Ten replicate blocks were prepared. Blocks were placed perpendicular to the current in a section of Hopewell Run, a second-order stream in Jefferson County, WV, with fairly homogeneous water depth and velocity. The blocks were randomly rearranged weekly to ensure equal exposure to variations in flow conditions. Tags were examined after 16 wk to evaluate legibility and retention.

Tumbler Test

A minimum of four examples of both tag types were applied to mussel shells using cyanoacrylate, which was allowed to cure for 2–3 min then was immersed in water. To fully test the durability of the tag material and printing, care was taken to avoid placing adhesive on the surface of the tags. After remaining in water for approximately 24 h, individual shells were placed in a rock tumbler (Natural Science Industries, Far Rockaway, NY) containing 38 g of coarse metal shavings. The tumbler was operated for 1 wk with periodic examinations.

Field Tests

Shellfish tags were attached to live mussels with cyanoacrylate and were monitored at a site on the Cacapon River in West Virginia. The site was 200 m long and was divided into 10 20-m long sections. Each section was searched for 30 min using viewing buckets, and all mussels encountered were removed from the substrate for identification, measurement, and tagging, then they were returned to the substrate in the same section where they were found. Each animal was double-tagged with one tag placed on the posterior slope of each valve. The area of tag application was cleaned with a medium grit sandpaper or scrub pad, then was rinsed and blotted dry. A small amount of cyanoacrylate was applied to the shell (i.e., a volume sufficient to completely attach the tag with minimal excess glue), then, using forceps, the tag was placed on the adhesive and pressed gently.

The adhesive was allowed to air dry for at least 2 min before returning the animal to the water. The initial survey and tagging were conducted in July 1996, with subsequent surveys conducted in January, April, June, and October 1997, and in June 1998. Additional animals were tagged at each interval. Water temperature and turbidity were measured during each survey.

RESULTS

Evaluation of Adhesives

The characters on the fingerling tag were normally readable without magnification. The characters on the visible implant tags, however, are approximately 0.7 mm in height and were most easily read with the aid of a magnifying lens. Regardless of tag type (Fig. 1), the epoxy did not perform well, becoming cloudy when immersed for times < 15 min. Legibility in the 15-min group was impaired by the roughness of the surface of the adhesive. Additionally, the epoxy remained soft and was easily abraded during examination.

The printing on the visible implant tags dissolved in cyanoacrylate, resulting in complete loss of legibility in all tags in this treatment. Cyanoacrylate provided good visibility with the fingerling tags regardless of time to immersion, although minor surface rippling was noted in the groups immersed 2 and 5 min after application.

Evaluation of Tags

Instream Immersion Test

The adhesive covering the tags acted as a substrate for the attachment of silt and periphyton, somewhat impairing visibility. It was frequently necessary to scrape the surface of the glue to remove attached material. In some cases, it was necessary to remove the glue from the surface of the tag by gently scraping with a knife. There was no loss of legibility after surface materials had been removed. Tag losses for shellfish tags and fingerling tags were 5.3% and 2.6%, respectively, with no apparent relationship to the four drying times prior to immersion.

Tumbler Test

Neither tag type showed significant wear when compared to new tags, and no tags were dislodged during the tumbling process. As an extreme test, a shell with a shellfish tag was tumbled for an additional 3 wk with metal shavings, plus 4 wk with up to 100 g of sand in the chamber, and still did not show any appreciable wear.

Field Tests

Between June 1996 and October 1997, 1,372 mussels were tagged at the Cacapon River site. Species consisted of predominantly *Elliptio complanata* (Lightfoot, 1786) (85.6%), *Elliptio fisheriana* (Lea, 1838) (7.7%), and *Lampsilis cariosa* (Say, 1817) (5.9%) and a few individuals of *Alasmidonta varicosa* (Lamarck, 1819), *Lasmigona subviridis* (Conrad, 1835), and *Strophitus undulatus* (Say, 1817) (total < 0.9%). During periodic surveys through June 1998, 325 tagged mussels were recaptured. The time at large for recaptures ranged from 69 to 722 days. Survey temperatures ranged from < 0 to 24°C, and turbidity ranged from 1.4 to 14.3 NTUs.

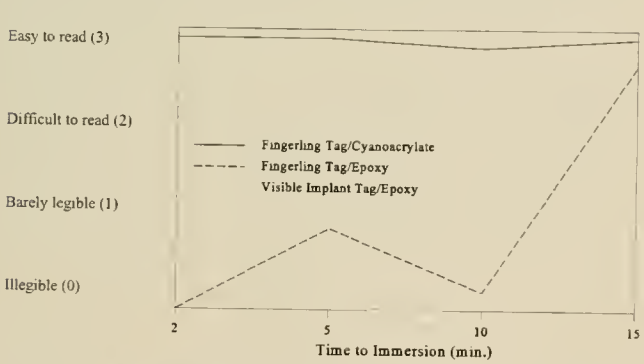

Figure. 1. Mean legibility of tag and adhesive combinations (numeric score) after immersion in water.

Only three tags were lost (0.46% of all tags recovered); two were missing when recaptured after 70 and 378 day *in situ*, and one was rubbed off while removing an attached caddisfly case after 447 day *in situ*. Loss of legibility was observed only once, after 69 days *in situ* (0.15%) and may be attributed to a printing error that was not recorded at the time of tagging. Additionally, six tags (0.92%) were reported to be loose when examined 69–343 days after tagging. Typically, one end of the tag was not well-adhered to the shell surface.

DISCUSSION

The results of this study indicate that the shellfish tag adhered with cyanoacrylate provides a good long-term marking method for freshwater mussels. While any tag loss is undesirable, the minimal losses observed in the field tests would not seriously affect population estimates based on these surveys. Conducting tests in the laboratory eliminated the need for trial and error exercises in the field and allowed the establishment of protocols before project initiation. This testing process eliminated an adhesive with undesirable characteristics, avoiding tag losses and illegibility that may have impacted long-term studies.

Although the two-part epoxy formed a clear, hard bond after a 15-min drying time, we felt that this was too long for safe handling of the mussels and would adversely affect the efficiency of field survey operations. Cyanoacrylate bonded quickly and was preferable because it did not require mixing. We also found that it was not necessary to cover the tag with adhesive, as the tag surface and printing are highly durable. Tumbler tests indicated that the printing on both tag types is of sufficient durability that complete coverage of the tag with adhesive is unnecessary. Clear adhesive, however, is still desirable in the event that glue gets on the tag surface.

Tag retention was greater in the field tests than in the instream immersion tests. Because old shells collected in previous surveys were used, higher losses may have been associated with a decrease in the integrity of the shell surface, even though the shells had been stored in water prior to tagging. In addition, tags on empty shells were more exposed to flowing water than those on live animals that could burrow into the substrate. Although water conditions were measured in both the stream immersion test and field tests, they were measured only at the observation intervals and may not reflect the full range of conditions. The evaluation of adhesive durability under different water conditions (e.g., temperature range, hardness, and alkalinity) should be undertaken in the future.

For our freshwater mussel surveys, shellfish tags are preferred over the fingerling tags for several reasons. Primarily, they are much thinner, reducing the opportunity for objects to snag on the tag edge. Treble et al. (1993) suspected that losses of tags were caused by abrasion and snagging as limpets moved through narrow crevices. Shellfish tags are also available in a wider range of colors, including subdued natural colors that may reduce visibility to predators (e.g., gray and beige). In addition, they use a combination of letters and numerals, which provides a large number of

individual codes for each tag color. Finally, the shellfish tags come on a roll, rather than loose, making them easier to handle in the field.

While costly in terms of the number of tags and the time to mark, the use of double tags will benefit large-scale, long-term tagging programs. It will allow a continuous evaluation of tag losses, the rate of which may change over time (Treble et al. 1993). Establishing rates of tag loss will provide correction factors for population estimates based on recapture of tagged individuals (Seber 1982, p.94). Because entire tags can become obscured by algae, insect cases, and other materials, the use of two tags also may increase the possibility that a tagged animal is recognized. Although these tests were physically rigorous, it is uncertain how long the adhesive will be effective. Differences in tag retention among species due to morphology (e.g., periostracum texture or animal size) and behavior (e.g., substrate preference or burrowing depth) are also unknown. Long-term monitoring and reporting to the research community will aid in the development of future tagging programs.

ACKNOWLEDGMENTS

We thank W. Bartles, A. Dunn, C. Horton, J. Lambert-Newman, M. Morton, P. Pooler, N. Thomsen, K. Voges, and P. Young for their assistance in the field. We also thank the tag and adhesive vendors who provided valuable technical information on their products, and in some cases, provided free samples for testing. Reviews of the manuscript by J. Layzer, W. Lellis, E. Pendleton, and K. Welke are greatly appreciated.

BACTERIAL PATHOGEN CONTAGION STUDIES AMONG FRESHWATER BIVALVES AND SALMONID FISHES

CLIFFORD E. STARLIPER[1] AND PATRICIA MORRISON[2]

ABSTRACT A part of the conservation efforts of native freshwater bivalves is a relocation program whereby animals are collected and moved to a safe refuge for maintenance and propagation. With the rearing of two different hosts, mussels and fish, on the same facility there is a question of the possibility for contagion of pathogens. The studies presented here are part of a continuing effort to address the concerns of contagion. Freshwater bivalves collected throughout the 1997 season were cultured for fish pathogens. Counts of total bacteria on cytophaga medium ranged between 1.07×10^5 and 4.99×10^5 cfu/g of mussel soft tissues. The predominate groups of bacteria were motile *Aeromonas* spp. and *Pseudomonas* spp., both of which include members that are opportunistic pathogens to salmonid fishes. No primary fish pathogens were cultured; however, cells with correct morphology for *Renibacterium salmoninarum*, cause of bacterial kidney disease, were detected from mussel soft tissues in all six trials using the direct fluorescent antibody test. Groups of mussels were subjected to 24-h waterborne challenges using bacteria cultured from healthy fish; no mortality occurred to any of the animals. Another group exposed to the fish pathogen *Aeromonas salmonicida* also showed no effects of the challenge; however, susceptible fish became infected and died after the fish were added to cohabit with this group of mussels.

KEY WORDS: Freshwater bivalves, salmonid, pathogen, disease, contagion, bacteria, cohabitation

INTRODUCTION

Over 70% of the approximately 300 species and subspecies of freshwater bivalves (*Unionidae*) native to North America are categorized as endangered, threatened, or of special concern (Williams et al. 1993). Bivalves are particularly susceptible to impacts from environmental changes, not only because they are sessile, filter-feeding animals, and adverse effects placed on their intermediate fish hosts that are necessary for glochidia development also may indirectly affect them.

A number of factors have been documented as contributors to the decline in numbers of freshwater bivalves. Human disturbance in the terrestrial environment, such as agriculture and development, result in siltation that may impair growth and respiration and lead to suffocation (Ellis 1936, Kat 1982). Also, habitat alteration from dredging or dam construction can result in changes in flow or temperature and also affect movement of the intermediate fish host (Fuller 1974; Keller and Zam 1990). In recent years, the zebra mussel (*Dreissena polymorpha*) has become a major threat to native bivalve populations in large river systems (Herbert et al. 1991; Nalepa 1994). Zebra mussels are able to proliferate and compete very favorably against native animals (Gillis and Mackie 1994). Their high spatial tolerance allows them to colonize in great numbers, leading to mortality of native bivalves by impeding feeding and respiration (Griffiths et al. 1991, Haag et al. 1993, Leach 1993, Mackie 1991). In 1996, densities of zebra mussels in the lower Ohio River (near river mile 814) exceeded 14,000 per square meter, and mortality to the native populations exceeded 30% (P. Morrison, Ohio River Islands National Wildlife Refuge, U.S. Fish and Wildlife Service, pers. comm.).

In the mid 1990s, the U.S. Fish and Wildlife Service (USFWS) along with other federal, state, and private partners initiated conservation efforts. One such program was to isolate native animals from impending zebra mussel infestation from selected large rivers. Under this program, individuals are collected and relocated to safe refugia for maintenance and propagation with the hope of future successful reintroduction. These refugia, which are free of zebra mussels, include salmonid fish-rearing hatcheries, which may culture such species as rainbow (*Oncorhynchus mykiss*) and brook (*Salvelinus fontinalis*) trout. With the rearing of these two hosts (mussels and fish) on the same facility, there exists the possibility for contagion of pathogens either by shared water or via contaminated equipment such as boots, nets, and buckets. The question of contagion is particularly relevant, because one of the two hosts (freshwater mussels) is originating from a natural environment and might be exposed to pathogens of both mussels and fish that could be introduced to a hatchery along with their relocation. All of the recognized primary bacterial pathogens of salmonids involve, to varying degrees of significance, horizontal transmission, and, hence, there is a potential to develop disease in fish that might be exposed to pathogens via contamination or by some vector. It can be speculated that bivalves may serve as a pathogen vector. On the other hand, it is not known if certain microbial flora of healthy resident fish might pose a disease threat to mussels once they are exposed to the pathogen, and they are reared in intensive culture situations. There are no single pathogens described that produce disease in both salmonid fishes and freshwater bivalves. There is a wealth of knowledge on diseases to salmonids, but there are few reports of diseases and epizootics that occur in native freshwater bivalves. However, it has been demonstrated that freshwater mussels may serve as a vector for fish pathogens, because *Flavobacterium columnare*, the cause of columnaris disease, was isolated from a single *Amblema plicata* that was collected from the Ohio river (Starliper et al. 1998).

Presented here are studies that are part of a continuing effort to evaluate the potential for contagion of bacterial pathogens. We report on efforts to isolate salmonid bacterial pathogens from freshwater bivalves that were collected from their natural environment (without quarantine), and to produce disease or mortality

experimentally in bivalves using the representative bacterial flora from healthy fish and two fish bacterial pathogens.

MATERIALS AND METHODS

Freshwater Bivalves and Fish

All bivalves were collected by brailing between August and November 1997, and this duration was representative of that year's sampling season. Duration of sampling seasons varies from one year to another, depending upon water temperature and when animals emerge from the river bottom. The collection site was between river miles 175 and 177 at Muskingum Island of the Ohio River, which is near Boaz, Wood County, West Virginia. This region of the river is not easily accessible by land, and the only public use is pleasure boat traffic. The site supports 28 species of freshwater mussels, including two federally listed species (*Lampsillis abrupta* and *Cyprogenia stegaria*). The island and its underwater acreage, including the mussel beds, are protected from development, because it is within the Ohio River Islands National Wildlife Refuge. No harvesting or collecting of mussels is allowed on the refuge except for scientific or management purposes.

Bivalves used to evaluate the presence of fish pathogenic bacteria were collected at 2 to 3 week intervals during this season. Twenty animals were collected on each of six dates (trials 1–6, respectively), except for trial 6, when only eight were collected because of low water temperature. Upon collection, animals were kept cool and moist and shipped overnight by commercial carrier to our laboratory for bacteriological analysis the following day. They were not placed in other water in the interim between collection and analysis. Species and physical data for the bivalves represented in this study are presented in Table 1. Also, the distribution data for *Amblema plicata*, which was the species most frequently collected during the season, are given in Table 2. Ohio River surface water temperatures (°C) were recorded at the time and collection location for each trial.

Two hundred animals, representing six species, were used as subjects for bacterial challenges with flora isolated from healthy fish: *A. plicata* (123), *Quadrula metanevra* (33), *Q. quadrula* (21), *Obliquaria reflexa* (10), *Q. pustulosa* (9), and *Pleurobema cordatum* (4). Physical data of the animals used in the challenge studies are not presented; however, mean values were very similar to those animals used for fish pathogen isolation, which are presented in Tables 1 and 2. These animals were quarantined for 30 days at the Ohio River Islands National Wildlife Refuge (Parkersburg, WV) to eliminate any zebra mussels (Gatenby et al. 1998). They were then transported to the Leetown Science Center, where they were acclimated to (over 2–3 hours) and maintained in pathogen-free spring water (12 °C) delivered via a flow through system.

The fish added to the tanks to cohabit with mussels following their (mussels) challenge were the Nashua strain of brook trout (*Salvelinus fontinalis*), about 50 g each, and the Shasta strain of rainbow trout (*Oncorhynchus mykiss*), also about 50 g each. The fish were certified as fish pathogen-free through biyearly fish health inspections by the U.S. Fish and Wildlife Service's Fish Health Unit, Lamar, Pennsylvania. The fish were maintained in the same water as described for the mussels; all *in vivo* studies were also done using the same water source.

Collection and Processing of Tissues from Bivalves

Tissues were collected and prepared using a procedure similar to that developed by Starliper et al. (1998). The external shell surface of each animal was cleaned by brushing with 200-ppm chlorine, rinsed in deionized water, and allowed to dry. An oyster knife was used to pry open the shell valves, and the adductor muscles were cut. All soft tissues were excised from the shells and were separated into two samples. One consisted primarily of digestive tract tissues, denoted "gut" (e.g., stomach, intestine), while all remaining soft tissues, denoted "OT" or other tissues, (e.g., mantle, gill, foot, lymph) comprised the second. The gut sample was removed first, and effort was made not to contaminate the remaining tissues with bacterial contents from the gut. Soft tissue samples were placed in preweighed, sterile stomacher bags. The bags with tissues were weighed, and the difference of the two weights was the weight of the tissue sample.

Isolation and Growth of Bacteria

For bacterial isolation, the tissue samples were diluted in sterile 0.1% peptone- 0.05% yeast extract (PEP-YE). To each sample, a volume (mL) of PEP-YE equal to the tissue weight (g) was added yielding a 1:2 dilution of tissues. This was homogenized for 120 seconds using a Model 80 stomacher (Seward Medical, London SE1 1PP, UK). A portion of the supernatant from each homogenate was transferred to a sterile tube for ease of handling and three serial tenfold dilutions were prepared from this, also in PEP-YE. Four drops (0.025 mL each) from all dilutions were applied to the surface of each bacteriological medium. After the drops had been adsorbed, plates were incubated at the appropriate temperature and duration specified in the appropriate reference materials (see Media employed). Following incubation, colonies were enumerated by counting the lowest dilution with single colonies, and this was converted to a standard colony forming units per g of tissue (cfu/g). For the selective and/or differential media used for specific

isolation of pathogens, suspect colonies that were picked to fresh media had their identity confirmed as to that particular pathogen, or not. Biochemical tests employed for bacterial characterizations were described in the appropriate reference papers or with standard biochemical characterization (Koneman et al. 1988; MacFaddin 1980). The sets of 1:2 dilutions were used to prepare smears on microscopic slides for detection of *Renibacterium salmoninarum* cells using the direct fluorescent antibody test (FAT; Bullock et al. 1980) and commercially available FITC-conjugated antiserum prepared in goats to the whole cells (Kirkegaard and Perry Laboratories, Inc., Gaithersburg, MD). One hundred microscopic fields of view were observed from each stained homogenate at 1,000× magnification using a Reichert Diastar Model 420 microscope with a halogen light source (Cambridge Instruments Inc., Buffalo, NY). An *R. salmoninarum*-positive kidney tissue from a diseased salmon served as a control slide for reference to the correct cell morphology.

Isolation of *A. salmonicida* from fish that died as a result of cohabitation with *A. plicata* that were previously challenged with the bacterium was done using a sterile inoculation loop to collect kidney tissue, and this was used to inoculate primary isolation plates. The medium for isolation of *A. salmonicida* was tryptic soy agar (TSA; Difco Laboratories, Detroit, MI) supplemented with 0.01 % coomassie brilliant blue (CBB; Cipriano and Bertolini 1988). The identities of suspect, blue colonies were confirmed as *A. salmonicida* with standard biochemical characterization tests.

Bacteria used for the waterborne challenges of bivalves were isolated from rainbow trout at the White Sulphur Springs National Fish Hatchery, White Sulphur Springs, WV. This facility was selected, because mussels are currently being held there, and the resident populations of fish are healthy and well maintained; therefore, they would be representative hosts of normal flora bacteria that relocated mussels encounter, either via the fish as a source or from their common water supply. Mucus and kidneys from 100 randomly selected rainbow trout were used to inoculate BHIA and CYTO plate media (described in Media employed). The resulting bacterial growth on the primary isolation media was observed, and the most frequent colony types, on the basis of morphology, were noted. Subcultures of the predominate bacterial types were established by transferring representative single colonies onto fresh plates. These isolates were used to challenge the groups of freshwater bivalves.

Media Employed

Thirteen media were employed to isolate bacteria, including fish pathogens from mussels. These media are routinely used by fish health personnel to culture environmental bacteria commonly found on fish or in aquatic environments and for isolation of specific pathogens. Two were used to determine total bacterial counts, brain heart infusion agar (BHIA; Difco Laboratories, Detroit, MI) and *Cytophaga* agar (CYTO), a medium of reduced nutrient concentration (Anacker and Ordal 1959); plates were incubated at 22 °C for 48 hours. An additional set of CYTO plates were incubated at 15 °C for culture of *Flavobacterium psychrophilum*, cause of bacterial coldwater disease of salmonid fishes (Bernardet et al. 1996). The cooler incubation temperature is favorable for growth of *F. psychrophilum*, and it also retards the growth of other, environmental bacteria that facilitate isolation. Three media were used for Gram-positive bacteria. Rogosa SL (ROGO; Difco Laboratories, Detroit, MI) was used for *Lactobacillus* and related genera. Azide blood agar base (ABA; Difco Laboratories, Detroit, MI) containing 5% sheep erythrocytes (Bio-Whittaker, Walkersville, MD) was used for other species, including *Streptococcus* spp. and *Staphylococcus* spp. Incubation of ROGO and ABA plates was at 28 °C for 3 days. A third, the selective medium (SKDM) described by Austin et al. (1983), was used for isolation of *R. salmoninarum*, cause of bacterial kidney disease (Bullock and Herman 1988). To enhance growth of this bacterium, the sterilized SKDM was cooled and supplemented with 1% filter sterilized culture metabolite (Evelyn et al. 1990) before pouring plates. Following incubation at 15 °C for up to 4 weeks, suspect *R. salmoninarum* colonies (Sanders and Fryer 1980) were suspended in 0.5 mL PEP-YE; 100 µl of this was placed on a microscopic slide and air dried. The dried smears were subjected to the direct fluorescent antibody test, as previously described. Other media used were for isolation and enumeration of Gram-negative fish pathogenic bacteria and unless indicated, were incubated at 28 °C for 2 to 3 days. Two were for isolation of *Yersinia ruckeri*, cause of enteric redmouth disease. They were the differential medium described by Waltman and Shotts (SW; 1984) and the differential and selective medium of Rodgers (ROD; 1992). Suspect colonies were transferred to TSA. Two media were for *Aeromonas* spp. One was CBB for *A. salmonicida*, cause of fish furunculosis; these plates were incubated at 22 °C; suspect blue colonies were transferred to TSA. The other medium (SGAP-10C) was for growth and enumeration of motile *Aeromonas* spp. (Huguet and Ribas 1991, Jenkins and Taylor 1995). Although other organisms may grow on SGAP-10C, such as *Pseudomonas fluorescens*, they are easily distinguished from *Aeromonas* spp. by colony characteristics and additional biochemical tests, such as fermentation of glucose. *Pseudomonas* isolation agar (PIA; Difco Laboratories, Detroit, MI) was for growth of *Pseudomonas* spp., of which many members of this or related genera are commonly found in aquatic environments or as part of the flora of healthy fish. *Edwardsiella* isolation medium (EIM; Shotts and Waltman 1990) is both differential and selective and was used for *Edwardsiella ictaluri*, cause of enteric septicemia of

catfish, and *E. tarda*, a potential pathogen often found in warm- and cold-blooded animals. Selective *Cytophaga* agar (SCA; Hawke and Thune 1992) was employed as a selective medium for *Flavobacterium columnare*, these plates were incubated at 37 °C for additional selection.

Challenge Procedures: Mussels and Fish

For the bacterial challenges of mussels, 20 tanks (27-L each) were used, each containing 10 mussels. The 200 animals, listed previously, were distributed equally by species among the 20 groups. The animals were allowed to acclimate in the tanks for 2 d before challenge. Sixteen of the tanks received bacteria: this included 14 that were of the predominate normal flora from rainbow trout from the White Sulphur Springs Hatchery, seven that were originally isolated on BHIA, and seven from CYTO. Another two tanks were challenged with the known fish pathogens *A. salmonicida* and *R. salmoninarum*, and there were four control groups exposed, one each for the four sterile media used to grow the challenge bacteria. The challenge strain of *A. salmonicida* originated from a furunculosis-diseased Atlantic salmon (*Salmo salar*) from Vermont, and the *R. salmoninarum* isolate (ATCC33209) was from a Chinook salmon (*Oncorhynchus tshawytscha*) from Oregon. The normal flora bacteria were each grown in a 200-mL quantity of either BHI broth or CYTO broth, the same medium that was used for original isolation. *Aeromonas salmonicida* was grown in 200 mL of TS broth, and *R. salmoninarum* was grown in 200 mL of KDM2 broth. Cultures were grown for 48 hours, except for *R. salmoninarum*, which was grown for 14 days. A viable cell count was done for each culture, and this was determined by preparing sets of serial tenfold dilutions in the homologous broth medium, and drop inoculating known quantities on plate media. Colonies were quantified, and the number of cfu/mL of tank water at the start of the challenges was calculated. To perform a challenge, the water supply to the tank was turned off, the culture was poured and mixed in, and exposure was for 24 hours. Then, the water was turned on and allowed to rinse for 24 hours; then to each tank, 10 fish were added: five rainbow and five brook trout. The mussels and fish were then observed for a period of 21 days for mortality and development of abnormal signs or pathology. Kidneys of fish that succumbed were cultured onto the appropriate medium, and subsequent bacterial growth was identified to confirm re-isolation of the bacterium used to challenge the mussels.

RESULTS

Physical data on the animals collected for isolation of bacteria are presented in Tables 1 and 2. The predominate bivalve species collected for the six trials was *A. plicata*, accounting for 81.5 % of the total. The average weight of the animals varied, depending on species, and ranged from 25.7 g for the single *E. lineolata* to 294.7 g for the *A. plicata*. However, regardless of over-all size, the percentage of the total weight comprised of soft tissues ranged from 10.5 to 15.2 %. Of the total soft tissues, the ratios of our portioned gut to OT samples were also similar among the hosts. The percentage of soft tissues collected as gut samples ranged between 53 to 64 %, with the paired OT samples comprising the balance of the total soft tissues. With exception of trial 4, the distribution of *A. plicata* physical data remained relatively similar throughout the season (Table 2). In five of the trials, the mean weights of the *A. plicata* ranged from 247.6 to 294.7g; whereas, with trial 4, the average weight was less, 153.7 g.

Results of the bacteriological analyses including enumeration of bacterial flora, numbers and qualitative characterization of suspect colonies, DFAT staining for *R. salmoninarum* in tissue homogenates and Ohio River surface water temperatures at the time and location of collection for the six trials are given in Table 3. Total bacteria counts using the routine growth media BHIA and

TABLE 3.

Mean bacterial counts (cfu/g), colonies selected and characterization results of suspect fish pathogenic bacteria isolated from freshwater bivalves sampled six times (Trials 1–6) during the 1997 collection season. The data are mean or summary values for the number of animals per trial. Trials 1–5 had 20 animals each, trial 6 had eight.

Medium[a]	Trial 1 (29 °C[b])	Trial 2 (27 °C)	Trial 3 (24 °C)	Trial 4 (21 °C)	Trial 5 (20 °C)	Trial 6 (10 °C)
BHIA	1.07×10^5	2.90×10^5	2.31×10^5	2.10×10^5	2.85×10^5	2.01×10^4
CYTO at RmT	1.81×10^5	4.99×10^5	2.91×10^5	4.29×10^5	2.73×10^5	1.07×10^5
SGAP-10C	3.81×10^4	8.39×10^4	3.77×10^4	2.03×10^4	8.07×10^4	2.95×10^3
PIA	8.37×10^3	5.41×10^4	7.61×10^3	6.69×10^3	2.01×10^4	3.36×10^3
CYTO at 15 °C	NS[c]	NS	1 (0)[d]	14 (0)	NS	NS

[a] Media for total counts: BHIA, brain heart infusion agar; CYTO, *Cytophaga* agar; SGAP-10C, for motile *Aeromonas* spp.; PIA, *Pseudomonas* isolation agar. Gram-negative media: CYTO@15 °C, for *Flavobacterium psychrophilum;* SW/ROD, two media for *Yersinia ruckeri;* CBB, for *A. salmonicida;* EIM, *Edwardsiella* isolation medium; SCA, for *F. columnare*. Gram-positive media: ROGO, primarily for *Lactobacillus* spp.; ABA, azide blood agar; SKDM, for *Renibacterium salmoninarum;* DFAT, direct fluorescent antibody test for *R. salmoninarum* of 1:2 dilution of each tissue.

[b] Temperature of Ohio River surface water at time and location of collection.

[c] NS = bacterial growth, but no characteristic colonies present. NG = no growth.

[d] Number of suspect colonies picked for biochemical characterization or for SKDM, DFAT for *R. salmoninarum* (number positive).

[e] Number of samples with growth, mean cfu/g of those with growth.

[f] Number of tissues positive: number of positive cells per 100 microscopic fields of each positive sample.

CYTO remained quite similar throughout the sampling season, with exception of trial 6 for which counts were less, presumably because of the colder water temperature. The average bacterial counts on BHIA ranged from 2.01×10^4 to 2.90×10^5 cfu/g of soft tissue and for CYTO, the range was 1.07×10^5 to 4.99×10^5 cfu/g. The range for *Aeromonas* spp. isolated on SGAP-10C was 2.95×10^3 to 8.39×10^4 cfu/g; whereas, for *Pseudomonas* spp., counts on PIA were between 3.36×10^3 and 5.41×10^4 cfu/g of soft tissue. All of the *Aeromonas* spp. were presumptively identified as being of the motile *Aeromonas* spp. group, because the only member of this group that is nonmotile and considered significant with regard to fish disease is *A. salmonicida* and none of the suspect blue colonies transferred and characterized off CBB were nonmotile. The sum of bacterial counts off SGAP-10C and PIA accounted for a large portion of the total bacteria. The water temperature was lowest when animals were collected for trial 6, not only had the animals burrowed beneath the surface of the river bottom and limited the number collected but also resulted in the lowest counts for total bacteria, motile *Aeromonas* and *Pseudomonas*. Conversely, the highest cfu/g of tissue for these three groups of bacteria were all recorded on trial 2, when the water temperature was near the highest at 27 °C. The proportion of the total bacteria that was comprised of motile *Aeromonas* and *Pseudomonas* was also highest from trial 2.

A number of Gram-negative colonies suspected of being pathogenic for fish were selected off the media CYTO at 15 °C, SW/ROD, CBB, and EIM (Table 3). Suspect colonies were identified based on meeting criteria set forth in the specific references. After transfer and biochemical characterization, none was confirmed as being a fish pathogen. There were no characteristic *F. columnare* colonies cultured from any tissues of any of the trials. In a previous year this bacterium was isolated from an *A. plicata* that came from the same location in the Ohio River (Starliper et al. 1998). The selective Gram-positive isolation media, ROGO and ABA, supported very minimal growth relative to that of the media used for Gram-negatives. Bacterial growth was present on ROGO medium in three of six trials, but from only five of the 96 tissue samples assayed. The counts of the tissues with growth ranged between 8.0×10^1 and 1.2×10^2 cfu/g. Tissues from two of the trials showed growth using ABA medium and these were from only four of 80 samples with averages of 5.90×10^4 and 3.20×10^2 cfu/g for trials 1 and 2, respectively. Isolates selected from the ABA culture plates were also identified as α–hemolytic *Lactobacillus* and were catalase negative, and, therefore, differed from *Carnobacterium piscicola* (formerly *Lactobacillus piscicola*) that has been previously noted to cause disease and low mortality primarily in postspawning rainbow trout (Starliper et al. 1992). Only in trial 2 was there any bacterial growth of any tissue samples on both ROGO and ABA. Serological based observation of the 1:2 tissue homogenates for *R. salmoninarum* using the DFAT showed positive fluorescent cells of correct morphology from every trial. Trial 5 had the largest number of tissues (8 of 40) with at least one cell detected within 100 microscopic fields of view. The number of cells detected in those positive tissue samples was either one or two for most, but 40 cells were seen in 100 fields from one *Q. quadrula* OT sample. However, no bacterial colonies yielding fluorescent cells having correct morphology for *R. salmoninarum* were noted on SKDM primary isolation medium from these or any other tissue homogenates. One suspect bacterial colony from SKDM growth plates did yield excellent positive fluorescence, but the individual cells were too large to be considered of correct *R. salmoninarum* cell morphology; this was from a *Q. metanevra* OT homogenate.

At the start of the 24-hour bacterial challenges, the average number of viable bacteria was 5.31×10^6 cfu/mL of tank water for the seven groups of freshwater bivalves exposed to the selected normal flora bacteria isolated from fish and grown in CYTO media. There was an average of 4.89×10^6 cfu/mL of challenge tank water in the seven groups of animals exposed to the normal flora bacteria isolated and grown in BHI medium. There was 1.98×10^6 cfu/mL of tank water in the group exposed to *A. salmonicida* and for *R. salmoninarum*, there was 3.53×10^5 cfu/mL. During the actual 24-hour waterborne exposures, there was no mortality experienced in the bivalves. The only bivalve death in the duration of the study, a *Q. quadrula*, occurred on day 8 of the 21-day cohabitation with fish and was in the group exposed to the TSB medium control. There was no mortality in the brook or rainbow trout in any groups that were placed to cohabit with mussels previously challenged with the 14 bacterial types cultured from the White Sulphur Springs National Fish Hatchery. Also, there were no deaths of fish in the *R. salmoninarum* group or the four control groups exposed to bacteriological media only. However, in the group of animals challenged with *A. salmonicida*, mortality in brook trout began on day 8 of cohabitation, two more died on day 15, and the remaining one on day 21. One rainbow trout died on day 21. Of these dead fish, there were no external lesions produced, but there was extensive internal pathology indicative of a systemic, Gram-negative bacterial infection. There were elevated amounts of red, ascitic fluid, hemorrhaging of internal organs, and the hind gut was filled with yellow, pus-like material. Kidney tissues of dead fish inoculated onto CBB plates resulted in heavy growth with presumptive blue *A. salmonicida*. Single colonies were picked, and their identity was characterized as *A. salmonicida* with the following criteria, in addition to blue on CBB: production of brown, water soluble pigment on TSA, K/A on triple sugar iron agar, oxidase positive, nonmotile by the hanging drop method, gelatin liquefaction positive, and a negative ornithine decarboxylase. The greater mortality in brook trout was expected, because they are known to be more susceptible to *A. salmonicida* than are rainbow trout (Cipriano 1982). After the 21-day observation, kidney tissues of the surviving rainbow trout were streak plated onto CBB, and *A. salmonicida* was isolated and the identity confirmed, as previously, from two of the fish. The 10 mussels in this group were comprised of seven *A. plicata* and one each of *Q. metanevra*, *P. cordatum* and *Q. quadrula*. After the 21 days of cohabitation, the gut and OT soft tissue samples of each of these animals was excised, homogenized, and diluted as previously described with drop inoculation onto CBB plates for isolation of *A. salmonicida*. From these, no suspect colonies were cultured from any of the 20 soft tissue homogenates; therefore, *A. salmonicida* was not reisolated.

The 10 freshwater bivalves challenged with *R. salmoninarum* included seven *A. plicata*, two *O. reflexa*, and one *Q. pustulosa*. In contrast with the group challenged with *A. salmonicida*, no mortality in fish occurred. After the observation period, the fish kidney tissues of surviving fish were used to prepare smears on microscopic slides for evaluation by DFAT. No fluorescent *R. salmoninarum* cells were detected. At this time, the same was done for the gut and OT tissues of the ten mussels, and one *A. plicata* was positive with two cells of correct morphology for *R. salmoninarum* being detected in 100 microscopic fields viewed. However, it is not known if these cells were alive, beecause the DFAT stains both

live and dead cells. Upon observation of the slides prepared from the mussel tissues, there was a significant amount of small (1μ in diameter) fluorescent particles present that did not have uniform shape and were not confused with intact cells. There were too many, and each was too small to be quantified accurately. It is not known if these entities in some way originated from the *R. salmoninarum* cells used for challenge or if they were artifactual staining. In either case, this is unique, because this is not typically noted on stained slides prepared from fish kidneys, whether the tissue is positive or not for the bacterium.

DISCUSSION

With intensive fish culture and fish health management, the best defense against pathogenic diseases is prevention (Piper et al. 1982). All of the major bacterial pathogens of salmonid fishes may involve horizontal transmission. This might occur among resident individuals within a facility or could result from introduction of a pathogen to resident fish by contamination with a new lot of fish placed into the facility. Relocated fish could be carriers of a pathogen and because of their past exposure may have some innate immunity that would allow them to harbor an organism and not display any obvious signs of disease. Then, when naive fish are exposed to bacteria shed by the carriers, an epizootic may ensue. Because of this potential, it is imperative that fish to be relocated undergo a health inspection to identify pathogens, including those that are not obvious because of a lack of clinical signs. The potential for introduction of pathogens via relocated freshwater bivalves is also of concern. Animals may be originating from open and uncontrolled environments, such as the case with those from the Ohio River, where they might be exposed to wild fish that could be diseased. Bacteria are shed into the environment and the bivalves could uptake bacteria either as a food source or by simply filtering contaminated water. The primary pathogens of salmonid fishes are not known to cause diseases in freshwater bivalves; therefore, animals would be unlikely to become carriers of a pathogen in the sense that susceptible fish can following their survival of an epizootic. Once freshwater bivalves are removed from the source (shedding) of a bacterial pathogen and relocated to a pathogen-free water supply, such as could be the case of quarantine for zebra mussels, the length of time the pathogen remains present and viable in the tissues and could still be infective to fish is not known. This is especially important considering the results of the cohabitation study where mussels were exposed to *A. salmonicida*. In a study by Plusquellec et al. (1994) with two marine bivalves, the mussel *Mytilus edulis* and the oyster *Crassostrea gigas*, retention of the enteric human pathogenic *Salmonella* following artificial exposure and air drying showed retention of viable cells of at least 5 days at 12 to 15 C and as long as 20 days at 10 C. However, when the clam *Mercenaria mercenaria* was artificially exposed to *Escherichia coli* or *S. typhimurium*, and the infected animals were moved to flowing, pathogen-free seawater, they are able to reduce viable cell loads in tissue homogenates within 24 hours by factors of 10^4 and 10^5, respectively, from a starting tissue load of between $1–2 \times 10^5$ cfu/g (Timoney and Abston 1984). A change in bacterial flora was similarly noted within 24 hours in freshwater bivalves that were not initially exposed artificially to bacteria, rather these animals were simply relocated from one water supply to another (Starliper et al. 1998). In this study, the total bacterial count per gram of soft tissue remained quite stable at both water sources, but the most notable change was a relative increase of nonfermenting bacterial types, coinciding with a decrease in other bacterial types after 24 hours of being in the different water supply.

The bivalves that were collected in trial 4 were smaller than those collected in the other five trials (Table 2). The smaller animals were several years younger than the larger ones. When collecting animals from a large environment, such as the case with the Ohio River, a group with size characteristics unique to other groups collected is not unusual. Bivalves are not evenly deposited on the river bottom, rather, they often occur clustered as to age and species, which has to do with the movement of the host and where the juveniles drop from the host. This is particularly relevant with *A. plicata*, because of the variety of fishes that may act as hosts and include many species of the family *Centrarchidae*, sauger (*Stizostedion vitreum*), and the flathead catfish (*Pylodictis olivaris*).

In the study by Starliper et al. (1998), *Flavobacterium columnare*, cause of columnaris disease in many cool and warm water fishes, was isolated from an *A. plicata*. This animal was assayed directly after being removed from the Ohio River and had not been placed into pathogen-free water for any time prior to analysis. The pathogen was not isolated from animals that were collected at the same time, and location but had been in pathogen-free, flow-through water for 24 hours. Alone, information on the isolation of a fish pathogen from a bivalve that could be intended for relocation to a salmonid rearing facility is discouraging. However, before relocation, if they undergo quarantine according to a protocol such as that of Gatenby et al. (1998) to ensure that zebra mussels are not inadvertently spread and if the animals are maintained in pathogen-free water, there is the chance that pathogens may be depurated during the quarantine. This is surmised from the demonstrated rapid change in flora after being moved to a different water supply and because *F. columnare* was not isolated from animals after having been relocated for 24 hours.

The detection of cells of correct morphology for *R. salmoninarum* from the DFAT of mussel tissue homogenates could become a concern for fish health managers of salmonid rearing facilities. This bacterium and the disease it causes, when in a population of fish, presents significant health management problems, because a primary means of pathogen transmission is vertical, in addition to the fact that it is horizontally transmitted. Therefore, presence of any fluorescent bacterial cells of correct morphology noted in fish kidney tissues or ovarian fluids of spawned fish is not good, particularly at those facilities that are involved with egg production and shipment. The nature of the bacterium's being very slow growing and difficult to isolate, especially in low numbers, only adds to the dilemma of fish health managers faced with the situation. When fish health inspections yield only minimal numbers of positive cells using the DFAT or minimal positive results from other serology-based assays in the absence of bacterial isolation or clinical disease signs in fish, management personnel are faced with difficult decisions on the health status of the population. Therefore, if relocated mussels might be determined to be a source of a bacterium that could result in positive cells by DFAT, regardless of a lack of culture isolation, a significant concern is realized. An important topic for further study would be to evaluate if a 30-day quarantine in a clean or different water supply would result in depuration of cells that may yield fluorescence.

In the six trials of the present study, the results using the DFAT and culture on SKDM for detection of *R. salmoninarum* from bivalve tissues were not in agreement; no cells were noted from culture; whereas, there were using the DFAT for tissues. Discrepancies of this sort are not uncommon using various methodologies for detection of this bacterium in fish (Cipriano et al. 1985; Teska et al. 1995). A number of factors contribute to this and include the slow and difficult nature of isolation and growth of *R. salmoni-*

narum, specificity and sensitivity of antisera, the host, and the extent of infection within a population of fish. Furthermore, the DFAT was originally developed as a method for quick, presumptive diagnosis of clinical bacterial kidney disease (Bullock et al. 1980) that would later be confirmed by bacterial culture. The advantage was that a DFAT could be done in hours, as compared to weeks for primary isolation. This affords quick intervention for fish health managers to control the disease and prevent further spread. With heavily infected fish, the two methodologies correlate well, but when used for relatively healthy, pathogen carriers, the agreement may decrease.

In the cohabitation group with mussels previously exposed to *A. salmonicida* and brook and rainbow trout, it is noteworthy that after 21 days, the bacterium was not re-isolated from the mussels' soft tissues. This is interesting, because there were infected and dying fish present in that tank water, and clinically diseased and carrier fish are known to shed viable *A. salmonicida* cells. However, with only four rainbow left at the end, the quantity of bacteria shed might have been too few to maintain bacterial presence within the *A. plicata*. Also, the normal flora of the mussels may have displaced and/or prevented further infection, because to mussels, it is assumed that *A. salmonicida* is merely an environmental organism and not pathogenic.

With the *A. salmonicida* challenge experiment, it is encouraging that after being exposed to a load of viable bacteria in the water that is greater than would occur naturally, the bacterium was not isolated from animals after the challenge's observation period. Again, it would be important to evaluate if the quarantine for 30 days to eliminate zebra mussels is sufficient for native bivalves to concurrently depurate fish pathogens. Additional topics for research are to extend beyond 24 hours the duration between when mussels are removed from bacterial exposure and when susceptible fish are introduced. Furthermore, the bivalves can be exposed to lesser bacterial cell concentrations and a more natural challenge method, those more analogous to what might be encountered in nature and then evaluate contagion. Also, a determination should be made on whether the bacterium enters the soft tissues or merely is contained in the fluid portion outside the soft tissues, but within the shell.

Following the challenge and cohabitation involving *R. salmoninarum* and when fish and mussels tissues were evaluated by DFAT, no cells were detected in fish, and only two were detected from one *A. plicata*. These results were not surprising for this bacterium. Reproduction of experimental bacterial kidney disease in a laboratory by contact exposure is very difficult and requires significant effort and time. Wolf and Dunbar (1959) were able to produce mortality in brook trout by a noninjectable challenge with *R. salmoninarum* only after fish were maintained in tanks with bricks in place as a means for abrasion, then the water level was dropped daily and viable cells were added. Still, it took 96 days for the first death. In another study, IP injection of brook trout with a number of viable cells similar to that per mL of tank water used in the present study, the mean days to death for the group of fish was about 28 days, and the first occurred on about day 25 (Starliper et al. 1997). Because horizontal or contamination infection to fish is difficult and because this bacterium has a limited host susceptibility range that is known to include primarily salmonid fishes, perhaps the chance for mussels to act as vectors is remote. Particularly, if mussels are able to rid the bacterium as noted in the present study when exposed to *R. salmoninarum*, that after 21 days in clean water only two cells were detected by DFAT of the soft tissue homogenates. Furthermore, the high frequency of fluorescent particles in the tissues might be indicative of cellular debris resulting from the bacterial cells being digested by the mussels.

All of the freshwater bivalves in these studies were used, because they are readily available, and they exist in high numbers; however, they may not be species that will be collected as part of the relocation program. Once techniques are developed using common animals and are available, the appropriate studies may then be repeated using minimal numbers of surrogates selected to represent those animals that do fit the criteria for relocation.

ACKNOWLEDGMENTS

Appreciation is extended to those facilities that provided pathogen-free fish: The Conservation Fund, Freshwater Institute, Shepherdstown, WV; Paint Bank State Fish Hatchery, Paint Bank, VA; and White Sulphur Springs National Fish Hatchery, White Sulphur Springs, WV. Also, thanks to Ms. Rita Villella and Dr. G. L. Bullock for their critical reviews.

ABSTRACT The present work shows that an artificial bait can replace the traditional baits (raw fish) using tuna by-products preserved with citric and phosphoric acids to produce an acid fish silage. After 2 months preservation by mixing minced viscera from the tuna industry with 2.6% each of citric and phosphoric acids, the silage was ready to be blended in two different mixtures; acid, or non-neutralized, and neutralized with 5% sodium carbonate to reach a pH close to 6. The baits were made by mixing both types of silage (non-neutralized and neutralized) with starch, fishmeal, and fish oil to prepare a sausage-like bait weighing 150 g each. A cellulose membrane was used to cover the bait and a cotton string to close them at both ends. After measuring the soluble protein loss at different times throughout 48 h, it was shown that baits leach out up to 0.88 mg protein per g bait per hour. Both types of bait did not show any significant difference compared to the natural bait (raw fish) when tested under commercial fishery conditions. The baits were also tested for dehydration by hanging until a 14% water content was reached. However, the dry baits showed a lower leaching rate when they were exposed to water. More experiments should be performed in order to conclude if dried baits are able to attract lobsters in a way similar to the moist baits.

KEY WORDS: *Panulirus*, lobster, artificial baits, baits

INTRODUCTION

The lobster is an economically important resource of Mexico, especially in Baja California, their principal area of capture (Briones and Lozano 1994). According to the Mexican foreign trade bank (Bancomext), 2,552 tons of lobster was captured in 1997 in Mexico, where the spiny lobster (*Panulirus interruptus*) was the most important species, which valued 22 million dollars. This placed lobster sixth in economic importance of Mexican export fishery products of 1997.

The fishery of lobster in Baja California it is one of the oldest fisheries in the region. In 1959, the fishery was given in concession to 19 cooperatives along the coast. In 1992, the private sector was allowed to catch lobster with a governmental permission or concession (Diario Oficial de la Federación 1992), but the lobster production still remained mainly cooperatives-controlled. Lobsters are caught from September to February, depending on the reproductive status of the animals. The lobsters are taken in traps, which usually contain two entrances and one compartment for the bait. Lobsters are nocturnal; therefore, traps are checked daily in the early morning during open season, at which time, the lobsters are removed, and the bait is replaced.

Bait is very important for this activity, because the fishermen depend upon a regular and quality supply. Bait generally consist of fresh or frozen fish, which is obtained either by the head office in the cooperative or the by fishermen, where sometimes a whole day is devoted to obtaining sufficient bait for the following day. They act as attractants by the leaching from the hydrolyzed protein or fluids from fish (Ache et al. 1978), which is sometimes increased by bacterial decomposition (Zimmer-Faust 1987; Zimmer-Faust and Case 1983; Zimmer-Faust et al. 1996). The fishermen choose their type of bait according to their prior experience with different fish or invertebrate species or size of the bait, which often results in longer periods of time to get their favorite bait. Cans with fish in tomato sauce are also sometimes used, where small holes at both sides of the can are made leaving the can for one or two days.

Baits are one of the main problems faced by this fishery since large quantities of fish must be stored in short term refrigeration facilities, resulting in large expenses for the co-operatives. One of the main co-operatives of the region estimate that up to $50,000 U.S. are used for baits during the season (Jacobo Castro, Cooperative head officer, pers.com.). Moreover, good quality fish suitable for human consumption are often used as bait, which has other implications. According to FAO demand for fish products is increasing and the use for certain products should be destined only to humans (FAO 1997). Besides the problems above mentioned the handling of fresh or frozen fish has considerable energy demands and also requires that fishermen collect their bait daily from the co-operative office. Fishery camps are sometimes far from the storage rooms from the head office, which makes this type of handling difficult.

Several artificial baits have been tried in order to substitute the fresh and frozen fish (Mackie et al. 1980; Carr 1986; Daniel and Bayer 1987; Miller 1990 and Mohan-Rajan and Shahul 1995), but for some reasons non-of them are commercially available. In the present work a new concept of bait is introduced, which uses tuna by-products preserved as acid silage extruded in a cellulose membrane.

MATERIAL AND METHODS

Baits Preparation

Tuna by-products were ensiled as described by Viana et al. (1993). In summary, chopped tuna by-products were mixed with 2.6% phosphoric acid, 2.6% citric acid and 0.1% sodium benzoate was added as a preservative. The mixture was blended to obtain a homogenate and left for 60 days in plastic buckets, while adjusting the pH lower to than 3.5. Further, the silage was separated in two

groups and one of them was neutralized using 5% sodium carbonate as described by Raa and Gildberg (1982) prior to cold mixing with the other ingredients as described in Table 1. The sausages were extruded in a pasta Machine (Rosito Bisani TR110) using a funnel and cellulose membrane. The sausages were tied with cotton string at both ends every 15 cm long, and were hang or frozen until used.

Lab analysis

Protein leaching

The baits were tested for protein leaching at 16 °C by immersing 30g baits in triplicate in 250 mL beakers containing 100 mL seawater at constant turbulence created by a horizontal lab mixer. A 1 mL sample of seawater was taken at 0, 6, 12, 24, 30, and 48 h and soluble protein content was determined. Soluble protein was estimated following the Lowry method (Lowry et al. 1951), using bovine serum albumin (BSA) for the calibration curve. The amount of soluble protein reported is expressed as mg protein equivalent to bovine serum albumin (BSA) per g bait.

Dry matter loss

The remaining dry matter was measured at constant dry weight by recovering the baits after 0, 6, 12, 24, 30, and 48 h immersion in seawater. Percentage dry weight was calculated as the dried residue weight of triplicate samples of each bait after drying to constant weight at 100 °C during 24 h.

Total protein

Total nitrogen was determined using triplicates samples analyzed by the Kjeldahl method (AOAC 1995). Crude protein was calculated as % N × 6.25.

Microbiological analysis

Baits were tested for bacterial content under storage at days 0, 8, 16 and 183. Baits samples were stored in plastic bags at 3–4 °C and total bacterial content was determined (Aerobic plate count APC) following the procedure described by the FDA-AOAC (1992).

Dehydration / Re-hydration tests

In order to determine the behavior of baits under storage, the baits were dehydrated when hanged at 3–4 °C until 15% humidity was reached. The dry baits were tested for time of re-hydration and tested for protein leaching as described before.

TABLE 2.

Proximate composition of the artificial baits tested in this study, given as percentage.

Ingredients	Tuna By-Product Silage (%)
Protein (g/100g)	27.4
Total lipids (g/100g)	11.9
Total solids (g/100g)	46.1

Fishing experiment

Both neutralized and non-neutralized fish silage baits were tested in the Co-operative of Emancipacion, BCS, Mexico during 6 days in January, 1996. For this, 150 neutralized and 60 non-neutralized baits were prepared while only 41 neutralized and 12 acid baits were tested in pairs together with a traditional bait (fish parts). Each bait (artificial or traditional) was introduced separately to traps in the early morning (5:00 AM) and 24 h later the number and size of lobster were registered.

Statistical procedures

A one way ANOVA (Zar 1999) was used to compare between baits, non-neutralized vs. neutralized tuna-fish silage. To test possible differences between treatments on leaching and stability at different levels of time an analysis of covariance (ANCOVA) was used according to Sokal and Rohlf (1981). To test the baits functionality in the lobster traps, a one way analysis of variance (ANOVA) was used to compare between non-neutralized and neutralized fish silages and traditional bait. The computer package of Sigma-Stat for windows, version 1.1 (Jandel 1994) was used in these statistical analyses.

RESULTS

The lobster baits showed a proximate composition of 27.4% crude protein, 11.9% total lipids and 46.1% total solids (Table 2). When the neutralized and non-neutralized baits were tested for leaching of protein no significant differences were observed be-

tween treatments at any time up to 48 h, as shown in Table 3. By a covariance analysis it was also corroborated that no differences were found in the rate of leaching being 0.84 and 0.88 mg/g/h, respectively.

The dry matter loss on non-neutralized baits showed a rate loss of 0.14 grams per 100 grams per hour up to 48 h. The loss for the first 24 h was below 5% (Table 4). Moreover, by measuring the remnant total protein it was shown a decrease in protein content over time, from 27.5% to 22.2% after 48 h with a rate loss of 0.11 g protein per 100 g per hour (Table 4).

The dehydration of baits to a constant 14.3% water content was reached after 40 days from the original of 54.1% (Table 5). Moreover, those dehydrated baits showed a significantly lower leaching of protein after being re-hydrated compared to the fresh bait (Table 6) with a leaching rate of 0.55 mg protein per gram bait per hour, compared to 0.88 observed in the fresh bait. Non-neutralized baits showed no significant growth of undesirable bacteria with a growth of less that 25 colonies per gram even after 183 days.

The Table 8 shows the results obtained in the field with traditional baits (fresh mackerel) compared to the non-neutralized and neutralized fish silage baits. No differences were detected between all three different groups with the lobster at commercial size. However in the small lobsters group (within the illegal size) differences were observed where the non-neutralized bait showed less attractant activity followed by the other two treatments, the non-neutralized and the traditional baits.

DISCUSSION

Tuna by-products are rarely used in Mexico, resulting in large amounts of products, which are often discharged, causing environmental problems in nearby cities. However, although fish silage has proven to be a good product as an alternative to fish by-products (Raa and Gildberg 1982), its production in Mexico has not been established. Notwithstanding, fish silage has been described as an ingredient in abalone feed formulation (Viana et al. 1996). The present work demonstrates that fish silage can be effectively used as an ingredient to formulate lobster baits without observing any significant difference compared to the fresh fish regularly use in Mexico as bait.

Fishermen use a piece of fish every day, which can weight between 500 g to 1 kg (Raul Celis, pers. comm.). This piece is changed every day in order to be attractant to lobster. The baits can be supplied from the Cooperative's head office or by the own fisherman. As stated before it is difficult to estimate the cost for bait use in the season for all co-operatives, but they need to change opinion to a better opportunity in order to be able to stand the market price fluctuations.

The fish silage baits presented here are easy to use and the price would be far less if fish by-products are used. No differences were observed in leaching and as attractants between neutralized and non-neutralized baits (0.84 and 0.88 mg protein/g/h, respectively), suggesting that neutralization with 5% sodium carbonate is not necessary. This means that production of bait will require fewer procedures while conserving the bait at low pH. Bacteria grow very easily in fish products due to their highly digestible protein and soluble carbohydrates. At lower pHs as in the acid silage it is known that essentially no bacteria will grow (Raa and Gildberg

1982). However, when the acid fish silage is combined with other feed ingredients the pH in the mixture approaches 6 depending of the type of ingredients (Rivero and Viana 1996). In the present work the non-neutralized baits mixed together with fishmeal and starch at low proportions bacteria failed to grow even after 183 days (< 25 colonies/g), which means that the presence of non-neutralized silage could effectively inhibit decomposing bacteria. This is considered of particular importance since food for human consumption needs to be free of microbes, it will be necessary to maintain baits and lobster under hygienic conditions during their fishery.

When baits are hang they can be reduce to humidity as low as 14% after 40 days. Even if leaching was observed after re-hydration, the amount that washed out was significant lower (0.55 compared to 0.88 mg protein/g/h). In the present work it was not tested the effect of dry baits as attractants and therefore it will be necessary to performed another experiment in order to conclude their effectiveness. In the meantime, baits can be packed in vacuum bags to avoid dehydration if longer periods of time are necessary to store without refrigeration as was done in the bacteria growth test. Both neutralized and non-neutralized baits performed similarly in terms of leaching, dry matter loss and for catching legal size lobster. However, in the field trial, small lobsters (illegal size) showed to be less attracted by the non-neutralized than that of the neutralized fish silage and traditional baits (6.91 compared to 12.63 and 16.32 lobster/trap, respectively). The reason is difficult to explain, but it could also be an advantage to catch fewer illegal size lobsters.

Although several types of baits have been tried before (Koyama et al. 1971; Cange et al. 1986; Huner et al. 1990; Miller 1990; Brown et al. 1995; Mohan-Rajan and Shahul 1995), none of them have been successfully used on a commercial scale. This could have been due to different reasons like the cost of those baits, hygienic conditions or space in the fishing boats. This bait presented here could be of importance since uses inexpensive feed ingredients and stores readily without refrigeration; are microbial safe and its size make it easy to handle in a small boat. Nevertheless, in order to make the present baits commercially available, the direct involvement of the Cooperatives will be necessary since they will be the principal or the only buyers of these type of baits since the lobster is on concession to them.

ACKNOWLEDGMENTS

Our thanks to the people of the Co-operatives Emancipación and Ensenada for their support in testing the baits in the field, specially to David Camacho. We also thanks to Dr. Armando Shimada for his valuable criticism on the statistics. This project was partially financed by Conacyt Project No. 0237-A9107. The author received a fellowship from the DGETI (Dirección General de Educación Tecnológica e Industrial).

ABSTRACT This study describes and compares lobster fishing and handling practices on various boats, transportation conditions between fishing wharfs and processing plants, and health assessments of lobsters followed from the time of harvest to the time of arrival at the processing plants during the spring and fall fishing seasons of Prince Edward Island, Canada. A total of 2,191 lobsters landed from 64 boats in 1997 were tagged and included in the study. Over 20 fishing and transport-level factors were monitored, and more than 10 lobster-level factors were assessed on market-sized lobsters. A significant increase ($P < 0.05$) of 7.1% in the proportion of lobsters with open wounds from the time of harvest to the time of entry in the processing plant was found during the spring season; whereas, the proportion of lobsters with vigor loss significantly increased by 2.5% ($P < 0.05$) during the same interval. Total hemocyte counts (THC) and hemolymph total protein (TP) levels were significantly higher in the spring than in the fall ($P < 0.001$). THC and TP also increased significantly ($P < 0.05$) from the time of harvest to the time of arrival at the processing plants, a period in which the lobsters were held out of the water. The prevalence of *Aerococcus viridans* infected lobsters was significantly ($P < 0.001$) higher in the fall season (10.4%) than in the spring season (5.5%). Lobster catches experienced significantly warmer, windier, and sunnier conditions in the fall season ($P < 0.05$). Mackerel was the bait most commonly used during both seasons, and gaspereaux were only used during the fall season. In the spring season, lobsters of different sizes were prevented from having mutual contact on more than 63% of the boats, but only on 18% of the boats in the fall season. Most spring fishers (83.1%) added water to the live-tank after all the traps were hauled, as compared to a majority of fall fishers (72.7%), who had no water in the live-tank at any time ($P < 0.001$). Finally, lobsters spent, on average, significantly ($P < 0.001$) more time on board fishing vessels in the fall than in the spring season.

KEY WORDS: Lobster, *Homarus americanus*, fishing practices, postharvest, health

INTRODUCTION

The lobster (*Homarus americanus*, H. Milne Edwards 1837) fishery is one of the most economically important fisheries in Atlantic Canada. Although Canadian landings reached a record peak in 1991 with more than 48,500 metric tons, they have remained more or less stable since 1992 at about 40,000 metric tons, with an estimated landed value of almost $400 million (Can) in 1997 (Fisheries and Ocean Canada 1999). In 1997, Prince Edward Island fishers landed a total of 8,096 metric tons (20.8% of total Canadian landings) with a value of more than $73.8 million (Fisheries and Ocean Canada 1999).

To supply the market with live product year-round, the industry holds live lobsters in captivity for various periods, ranging from a few hours to several months. However, preprocessing mortalities can cause tremendous losses. These losses have been estimated by the lobster industry to be in the range of 10–15% (Cawthorn 1997). The ability of the industry to maximize economic returns is reduced by lack of knowledge of factors contributing to these losses. Presently, there are no cohesive strategies that link all participants, from fishers to consumers, to detect and quantify production inefficiencies.

The lobster fishery is primarily a specialized in-shore small boat fishery (Pringle and Burke 1993). There is a consensus in the Canadian lobster industry that substantial variation in the quality of the product landed by different fishing boats and also among different fishing wharves is present. Variations in lobster health at the time of arrival at processing plants and storage facilities, and when lobsters are removed from short-term or long-term holding, can be partially attributed to conditions at the time of landing. Therefore, wharf-level factors and boat-level factors would directly influence lobster health. To understand fully the total variation of lobster health that is affected by fishing boats, further assessment at the boat level is needed. Paterson and Spanoghe (1997) suggested that sampling lobsters at various points of handling should yield valid information on stressors causing fatigue, weakness, and death. Following and assessing lobsters through the different handling points enabled the current study to produce a precise estimate of variation in individual lobster health. Identification of the frequency of losses and correlation to specific fishing or handling practices could contribute to better management. Subsequent reduction of losses, even by minimal amounts, could provide significant increases in economic returns to the lobster industry. Fishers, buyers, pound operators, processors, and exporters

might change their handling methods if provided with results that demonstrate which handling events affect productivity.

The primary objectives were to assess lobster health immediately after removal from the fishing traps, to reassess their health at the different handling points, and to describe fishing practices, handling events, and lobster transportation conditions with possible effects on lobster health in Prince Edward Island during the 1997 spring and fall fishing seasons. A subsequent paper (Lavallée et al. 2000) evaluates relationships between risk factors and lobster health.

MATERIALS AND METHODS

Several lobster health indices were monitored on fishing boats during the 1997 spring (May and June) fishing season in federally designated Lobster Fishing Areas (LFAs) 24 and 26, in Prince Edward Island. Lobster health was also monitored at wharves and processing plants where lobsters were handled. Sampling was repeated during the early part of the 1997 Prince Edward Island fall fishing season in LFA 25 (mid-August to mid-October). A total of 12 wharves in the spring season and three wharves in the fall season were included in the study.

Fishing Boat and Wharf Selection

A list of all lobster fishing wharves located in Prince Edward Island was provided by the Department of Fisheries and Oceans Canada (Charlottetown, PEI). A randomized sample of wharves taken from all lobster fishing wharves with more than 10 boats per wharf was computer generated (Minitab®, version 10.1, Minitab Incorporated, State College, PA, USA, 1994) and divided into two components based upon the fishing season: spring or fall. A brochure describing the project was distributed to fishers at each wharf sampled. Fishers were asked to accommodate an extra person on board to tag and assess lobsters landed on 1 day and also to monitor fishing practices. Fishers were free to decline participation. An average of two wharves were sampled each week, depending on weather conditions and fishers' cooperation. Fishers were selected randomly when more participants than needed agreed to cooperate. Sample-size determinations were based on the maximum expected number of boats on which fishing practices could be evaluated and lobsters tagged and assessed, according to the length of the fishing season (spring) and the availability of technical help (fall).

Lobster Selection

Only market-sized lobsters with a minimum carapace length of 81 millimeters (mm) were included in this study. Individual lobsters were identified by placing a 25.5 cm one-piece prenumbered plastic tag with a pull-tight seal (Ketchum Manufacturing Inc., Ottawa, ON) around the knuckle, proximal to the claw. Whenever sufficient lobsters were available, a sample size of at least 50 lobsters, based on the average number of individual market-sized lobsters expected per boat, was identified using this tagging method.

Physical Examination of Lobsters

Carapace length (measured in mm), sex, shell score (from 0 to 5, depending on the severity of the lesions), and physical condition index were recorded for every tagged lobster. Lobster physical condition index encompassed assessments of damaged or missing claws, legs and antennae, damaged body, open wounds, and vigor status (normal, decreased, or dead). These assessments were performed on the boats immediately after lobsters were removed from the traps. Body weight, recorded in kilograms (Accu-Weigh DSY-1000, Industrial Scales Ltd., Surrey, BC), shell score, and physical condition index were also measured on every tagged lobster at fishing wharves and at arrival at the processing plant, whenever possible.

Hemolymph Sampling

Hemolymph was sampled from a systematic random sample of approximately 15 lobsters per boat for determination of hemolymph total protein (TP), total hemocyte counts (THC), and evidence of *Aerococcus viridans* (causative agent of gaffkemia) infection status. Whenever possible, the same sampling procedures were repeated when tagged lobsters were landed at the wharf and after they reached the processing plant.

Using a 3-mL syringe with a 23-gauge needle, 1.6 mL of hemolymph was aseptically removed from the ventral sinus after swabbing the surface with 70% alcohol. THC were performed according to the method described by Horney et al. (2000): 0.5 mL of hemolymph was added to a 10-mL plastic tube containing 4.5 mL of artificial sea water (ASW) buffer with 0.1% formalin. The tubes were inverted 20–30 times and placed on ice until cell counts were performed with a hemocytometer (double dark line Neubauer improved counting chamber, la Fontaine, Dynatech, Germany) using light microscopy (Zeiss Standard 16 microscope, Germany) with a 40 power objective, by counting 20 squares per sample. The presumptive phenylethylalcohol (PEA) broth test was used for *A. viridans* isolation (Stewart et al. 1966) by adding 0.5 mL of hemolymph to 4.5 mL of PEA broth, vigorously shaking and incubating at 28 °C for 96 h. Duplicate PEA broth cultures were inoculated for each lobster. Suspicious broth culture tubes were identified by the typical purple to green to yellow color change of the broth, and confirmatory testing for the presence of *A. viridans* (tetrad-forming Gram-positive cocci) was performed using Gram stain and microscopic examination. The remaining 0.1 mL of hemolymph was placed on a temperature compensated refractometer for direct reading of total solid protein. The readings were then incorporated in the following formula to be converted to total protein as if measured by the biuret method (Horney et al. 2000):

$$\text{Lobster TP} = 0.898\ (\text{refractometer reading}) - 7.3$$

Assessment of Fishing Practices

A three-part data collection form was used on board each fishing boat from which lobsters were sampled. The first part, *Identification and Boat Specifications*, collected data on the crew size and number of years of experience of the captain or owner of the boat.

The second part, *Environment*, included information on air and surface water (less than 1 meter deep) temperature (°C). Strength (from none to storm), duration (in hours), and description of precipitation (intermittent or continuous) were recorded. In addition, this part included information on sunshine (in hours) and wave conditions (from none to >2 meters). Wind speed was also subjectively scored from 0 to 4 (0 = none, 1 = light, 2 = moderate, 3 = strong, and 4 = storm).

The third part of the data collection form, *Fishing Practices*, collected data on how lobsters were caught and handled on the boats. Bait used in the traps was classified as gaspereaux, mackerel, herring, flatfish, eel pout, redfish, crab, or other. The use of

a protective tarp over the lobster crates or totes, possible contact among lobsters before banding, having the lobsters loose on the deck at any point, and "packing over" and "dumping" of the lobster, either by the fishers or the buyers, were also evaluated. Packing lobsters over was defined as completely emptying a crate by taking each lobster one by one and repacking them into another container. Dumping lobsters was defined as transferring the entire crate or tote into another container simultaneously.

Holding units (small containers in which lobsters are first placed after being removed from the traps and after being graded/banded), and before and after grading were recorded as wooden crate, plastic tote, barrel, tray, polyvinyl chloride (PVC) tube, homemade box, other, or none. The live-tank system (large containers in which the holding units are placed) used on board the fishing vessels was recorded as none, "X-Actics™ box," fiberglass tank, or other. The presence of a lid while fishing and on the way back to the wharf was ranked as either none, partially on, or totally on. In addition, data were collected on the availability of water in the tank system while fishing and on the way back to shore, with the following six categories: "none;" "stagnant," where water was poured on the lobsters but with no flushing; "flow-through," where water was constantly pumped in the live-tank; "poured on," when water was poured on the lobsters and immediately flushed out; "ice," if the lobster were kept on ice; and "other." Furthermore, information was recorded on the maximum and minimum time a lobster could have been on the boat: the maximum time represented the period from when the first lobster was caught until the boat arrived at the wharf, while the minimum time was the same interval for the last lobster caught. The over-all handling of the lobsters on each boat was graded as either generally "placing" or "tossing" the lobster from the traps to the temporary holding units. Finally, the trap setting configuration used by the fishers was documented with four categories: single (one trap per buoy), double (two traps per buoy), multiple (more than two traps on a longline marked by two buoys), or a combination of the previous three methods. The depth (maximal and minimal) at which the traps were set was recorded in meters.

Assessment of Transport Conditions

The different transportation vehicles and conditions were also recorded by the investigators. Data collected included a general description of the vehicle and whether lobsters were transported in an open bed truck (pick-up truck), in a permanently closed transportation compartment (without refrigeration), or in a refrigerated transportation compartment. The outside temperature was recorded in degrees Celsius, and the weather conditions were subjectively described. Availability and of ice was noted as YES or NO, and the type of ice during transport was noted as either, freshwater or saltwater ice. The use of wooden crates or plastic totes was also recorded. Finally, the time interval between the fishing wharf and the processing plant and the total time the shipment spent in the vehicle were recorded in hours.

Statistical Analysis

All data collected were entered in a computer using spreadsheet software (Quattro® Pro version 7, Corel Corporation Limited, Ottawa, Ontario, Canada, 1996). A random sample of 120 records was examined for data entry errors by comparing against original datasheets. The dataset was transferred into a statistical software package (STATA™ 5.0, Stata Corporation, College Station, Texas, USA, 1996) for further analysis. Validation of data was done by obtaining descriptive statistics and looking for outliers. Frequency distributions were generated for each categorical variable and collapsed into dichotomous variables if obvious distribution patterns were seen. Analysis included descriptive statistics, binomial probability tests for gender ratios, Chi-square tests for comparisons of proportions, *t*-tests for comparisons of means in continuous variables, multiple comparisons (analysis of variance; ANOVA) with Bonferroni adjustments for categorical variables. For all analyses, differences were considered significant when $P < 0.05$. Results are presented as mean values ± standard deviation (SD), or proportions with the corresponding binomial exact 95% confidence interval (CI).

RESULTS

Fishing Wharves, Boats, and Lobsters Assessed

The number of tagged and sampled lobsters was limited by the daily catch. In total, 2,191 lobsters (1,672 in the spring and 519 in the fall) from 64 boats (53 in the spring and 11 in the fall) were examined. Approximately 74.5% (1,245 lobsters) of the lobsters tagged on board fishing boats during the spring season were followed to processing plants compared to 61.1% (317 lobsters) in the fall season. Finally, 36.4% (609 lobsters) of the lobsters examined on the boats in the spring had hemolymph sampled; whereas, this proportion was 31.8% (165 lobsters) in the fall. The compliance was excellent in the spring, with only one fisher out of 52 who were approached declining to participate; whereas, the fall compliance was fair with five fishers out of 16 declining to participate in the study.

Physical Examination of Lobsters

The sex ratio of tagged lobsters for the spring and fall seasons together was not significantly different than 1:1, with 52.0% females and 48.0% males ($n = 2,180$ and $P = 0.07$). However, the gender ratios differed significantly from a 1:1 distribution in the spring ($n = 1,665$) and the fall ($n = 708$): 44.5% of the lobsters were males in the spring compared to 59.4% males in the fall.

No significant seasonal differences in lobster body weight ($P = 0.708$) or carapace length ($P = 0.872$) were observed. Lobster body weight for both seasons ranged from 0.264 kg to 2.318 kg with a mean of 0.599 kg (±0.242 kg), and the mean carapace length for both seasons pooled together was 89.1 mm (±9.2 mm) and ranged from 77 mm to 154 mm.

With the exception of vigor, statistically significant differences were observed between the spring and the fall seasons in every physical index assessed, and these differences were present at every source of assessment with a consistent higher proportion of lobsters with normal indices in the fall (Table 1). Although no decrease in the proportion of lobsters with normal physical index was observed in the fall between the time of harvest and the time of landing or the time of arrival at the processing plant, some significant differences were recorded in the spring season. The proportion of lobsters with normal vigor at the processing plant was significantly lower than at the time of harvest or time of landing (Table 1). A significant increase in the proportion of wounded lobsters was also observed between the time of harvest and the arrival at processing plants, as reflected by the decrease in the proportions of normal legs and antennae at the processing

TABLE 1.

Percentage of lobsters with normal physical indices for each Zone, and at each assessment source during the 1997 spring and fall lobster fishing seasons in PEI.

	Lobsters with Normal Indices (%)	
Physical Indices	**Spring Seasnn**	**Fall Season**
Claws		
Boat	$85.3^{a,1}$	$93.1^{b,1}$
Wharf	$83.5^{a,1}$	$93.8^{b,1}$
Processing plant	$83.7^{a,1}$	$90.2^{b,1}$
Legs		
Boat	$93.7^{a,1}$	$98.1^{b,1}$
Wharf	$88.7^{a,2}$	$97.9^{b,1}$
Processing plant	$88.6^{a,2}$	$96.9^{b,1}$
Antennae		
Boat	$86.8^{a,1}$	$98.7^{b,1}$
Wharf	$85.7^{a,1,2}$	$97.9^{b,1}$
Processing plant	$82.8^{a,2}$	$97.8^{b,1}$
Body		
Boat	$93.1^{a,1}$	$96.9^{b,1}$
Wharf	$88.5^{a,2}$	$97.2^{b,1}$
Processing plant	$90.6^{a,1,2}$	$96.5^{b,1}$
Wound		
Boat	$87.9^{a,1}$	$94.8^{b,1}$
Wharf	$84.1^{a,1,2}$	$93.1^{b,1}$
Processing plant	$80.8^{a,2}$	$92.1^{b,1}$
Vigor		
Boat	$99.7^{a,1}$	$98.1^{a,1}$
Wharf	$99.1^{a,1}$	$98.6^{a,1}$
Processing plant	$97.2^{a,2}$	$96.9^{a,1}$

Significant differences are represented by different superscripts: letters within each row and numbers within each column. The normal score for the index "wounds" indicates the absence of wounds. In the spring, n = 1,672 on the boats, 866 at the wharves and 1,245 at the processing plants, and in the fall, n = 516 on the boats, 145 at the wharves and 317 at the processing plants.

plants. None of the lobsters assessed during this study suffered from shell disease.

Hematology

Hemolymph Total Protein (TP)

For every source of assessment (boat, wharf, and processing plant), the mean TP levels in the spring season were significantly higher than TP levels in the fall season for both male and female lobsters, with mean values ranging between 57.6 g/L and 70.5 g/L in the spring and between 31.9 g/L and 47.5 g/L in the fall (Table 2). Female lobsters had significantly higher TP levels than male lobsters at ever assessment source in the spring and also at the processing plant in the fall season, but male lobsters had higher TP levels at the wharf than females in the fall (Table 2). In the spring season, TP values of female lobsters were significantly higher at the time of landing than at the time of harvest (Table 2).

Total Hemocyte Counts (THC)

Significantly lower THC values were observed at the boat level during the spring season, as compared to the fall season; whereas, higher counts were seen at the time of landing in the spring, as compared to the fall season (Table 2). Similar to TP, some gender differences in THC were also observed in both fishing seasons: in the spring, the only significant difference between sexes was observed at the time of landing, with male lobsters having a mean THC lower than female lobsters. In the fall season, male lobsters also had lower THC than female lobsters at the time of arrival at processing plants, but had significantly higher THC than females at the time of harvest (Table 2). For both male and female lobsters during the spring season, significant increases in THC were observed between the time of harvest and the time of landing. Increases in females THC in the spring and fall were also significant between the time of harvest and the arrival at processing plants, while being significant only in the spring for male lobsters (Table 2).

Aerococcus Viridans Prevalence

The spring prevalence (n = 635) of *Aerococcus viridans*, the causative agent of gaffkemia was estimated at 5.33% (3.88%, 7.61%) and was significantly lower ($P < 0.001$) than the fall prevalence (n = 173) of 10.41% (6.28%, 15.95%). No significant difference in the prevalence of *A. viridans* according to sex in either season was observed.

Fishing Practices

Crew Size and Experience

There was no significant difference in the distribution of the size of the crew between the spring and fall seasons, and overall, the majority of crews consisted of fewer than three persons (Table 3). A significant difference between the two seasons ($P = 0.037$) was observed in the mean number of years of experience of the captain with fall captains being more experienced (Table 3).

Environmental Factors

The maximum and minimum air temperatures and the water temperature were all significantly lower ($P < 0.001$) in the spring than in the fall (Table 3). A significant difference ($P = 0.024$) was also found in the amount of sunshine during fishing, between the spring and fall seasons, but not in rainfall (Table 3). The amount of sunshine was greater than 6 hours on a majority of boats in the fall; whereas, the majority of spring boats experienced 6 hours or less. No significant difference was observed in the wave conditions or the wind velocity between season, and overall, the waves were estimated to be of an approximate height of one meter or less; whereas, on a majority of boats, the wind was scored as being none to light (Table 3).

Setting Configuratinn of Traps and Bait

Fishers used four different trap setting methods: single, double, multiple, or a combination of the previous three methods. A significant difference ($P < 0.001$) in the methods used was found between seasons (Table 3). For example, multiple traps per line were used on 95.6% of the boats in the spring, but never used in the fall fishing season. Significant differences were present between seasons ($P = 0.005$ for the minimum depth and $P < 0.001$ for the maximum depth), and both the maximum and minimum depths at which traps were set during the fall were greater than during the spring (Table 3). A significant difference ($P < 0.001$) was observed in the distribution of baits used between the two fishing seasons; although mackerel was the bait most commonly used in both seasons, gaspereaux was only used in the spring, and

TABLE 2.

Range, mean, and standard deviation of total hemolymph protein (TP) and total hemocyte counts (THC), according to the source of assessment and the fishing zone during the 1997 spring and fall lobster fishing seasons in PEI.

Variable	Source	Spring		Fall	
		Gender	Mean (SD)	Gender	Mean (SD)
Total protein (g/L)	Boat	Male	57.6 (14.3)^{a,1,†}	Male	39.8 (12.3)^{a,2,†}
		Female	65.4 (21.9)^{a,1,‡}	Female	40.5 (22.7)^{a,2,†}
	Wharf	Male	60.4 (12.5)^{a,1,†}	Male	38.9 (7.9)^{a,2,†}
		Female	70.5 (20.0)^{b,1,‡}	Female	31.9 (11.5)^{a,2,‡}
	Processing plant	Male	59.5 (12.4)^{a,1,†}	Male	40.7 (10.8)^{a,2,†}
		Female	65.6 (20.8)^{a,1,‡}	Female	47.5 (22.9)^{a,2,‡}
Hemocyte counts ($\times 10^6$ cells/ml)	Boat	Male	20.4 (8.5)^{a,1,†}	Male	25.3 (7.9)^{a,2,†}
		Female	20.8 (10.7)^{a,1,†}	Female	20.6 (7.3)^{a,1,‡}
	Wharf	Male	30.2 (9.2)^{b,1,†}	Male	27.8 (8.2)^{a,1,†}
		Female	33.4 (11.3)^{b,1,‡}	Female	26.9 (3.7)^{a,b,1,†}
	Processing plant	Male	30.3 (10.3)^{b,1,†}	Male	27.5 (8.6)^{a,1,†}
		Female	32.0 (15.8)^{b,1,†}	Female	31.3 (13.8)^{b,1,†}

Significant differences are represented by different superscripts: letters for the differences among sources of assessment for each both variables, in each gender and each season; numbers for the differences between season for both variables, in every source and each gender; and symbols († and ‡) for differences between gender for both variables, in every source and each season.

herring was used more often in the fall than in the spring lobster fishing season (Table 3).

Contact Before Banding and Over-all Handling of Lobsters

The proportion of boats on which physical contact among lobsters was prevented until they were measured and had their claws banded was significantly higher ($P < 0.001$) in the spring than in the fall (Table 3). Market-sized lobsters, after being removed from the traps, were generally tossed rather than placed into the temporary holding units on only 25% of the boats in total, and no difference was observed between seasons (Table 3).

Holding Unit and Live-Tank System

In both fishing seasons, the traditional plastic tote with a storage capacity of approximately 35 kg, represented the holding unit mostly used onboard fishing boats, whether it was before or after the lobsters were measured, graded, and banded (Table 3). Although no significant difference was noted between seasons in the distribution of the holding units used after grading, a difference ($P < 0.001$) was observed before grading; during the spring, the wooden crate was not used, as compared to more than 45% for the fall fishers. No difference between seasons was observed in the type of live-tank used on board the fishing boats, and overall, the fiberglass tank was mostly used (Table 3).

Water Availability and Lid Cover with the Live-Tank

In the spring, a majority of the fishers waited until all traps had been retrieved before adding stagnant water into the live-tank, and this practice was significantly different ($P < 0.001$) than during the fall season during which, most fishers never added water into the live-tank (Table 3). However, most fall fishers had the lid cover completely on the live-tank at any time; whereas, only 38% of the spring fishers had the cover completely on during fishing (Table 3). The difference between season in the lid availability distribution was only significant during fishing ($P < 0.001$), and not once all the traps had been retrieved.

Time on Board Fishing Boats

Only the maximum amount of time lobsters spent on board fishing boats was significantly different between the spring and the fall seasons ($P < 0.001$), with longer maximum time on board fishing vessels in the fall season (Table 3).

Transport Conditions

Transportation Vehicles and Ice with Transportation

A significant difference ($P < 0.001$) was present in the different vehicles used between spring and fall seasons to transport lobsters from wharves to processing plants (Table 4). During the spring, the vehicles mostly used consisted of trucks with refrigerated transportation compartments; whereas, in the fall, only closed trucks without refrigeration were used. Whenever ice was used around lobster crates or totes, it was freshwater ice, and during both seasons, a majority of shipments were sent to processing plants without ice.

Transportation Interval—Traveling and Shipping Intervals

The traveling and the shipping intervals showed significant differences ($P < 0.001$ for both intervals) between seasons, being shorter in the fall season than in the spring season (Table 4).

Air Temperature and Wind Velocity During Road Transport

The average temperature during transportation of lobsters from the wharf to the processing plant was significantly ($P < 0.001$) lower in the spring than in the fall (Table 4). It was also significantly ($P = 0.037$) windier in the fall fishing season than in the spring (Table 4).

DISCUSSION

The over-all compliance from the fishing and processing sectors of the lobster industry during this study was good, suggesting increasing concerns from the industry in lobster health-related issues. Although only market-sized lobsters were to be included in

[2] The minimum time represented the period from when the last lobster was caught until the boat arrived at the wharf.

this study, one canner-sized lobster (carapace length < 81 mm) was tagged and probably represents one canner-sized lobster that was misplaced by the fisher with the market-sized lobsters. Only the handling and fishing practices that showed substantial results are discussed. These include the lobster-level factors of gender, physiological indicators of health and vigor, environmental conditions, and boat-level factors related to traps and bait, holding and live-tank systems, and, finally, the over-all lobster handling. All remaining factors, including all transportation condition factors, did not show important variations and are not discussed further. The uneven distribution of wharves between the spring and the fall seasons was attributable to the limited time the investigators had to carry the study into the fall season. Because of the variation in sample sizes in the different fishing seasons, caution must be taken when comparing results from these lobster fishing seasons.

Physical Examination of Lobsters

Lobster Physical Conditinn and Vigor

The initial assumption was that lobster health status would being to decrease only after lobsters entered the traps. Most of the vigor loss occurred between wharves and processing plants, not between boats and wharves. Perhaps these vigor losses were induced by injuries inflicted on the wharves or even on the boats, but their effect was not detected until later. The fall fishing season is occasionally considered a lesser quality fishery because a majority of lobsters are in a postmolting softer-shelled condition. Therefore, the significant higher proportion of lobsters with normal physical

[1] Direct meant that no vehicle was used; the lobsters were landed directly at the processing plants.

indices in the fall compared to the spring season was unexpected, and the explanation is unclear.

Gender

Ennis (1978) found that the male–female ratio of large lobsters when sampled by scuba divers was 1:1, but when estimated through trap capture, the ratio was 3:1 in favor of male lobsters. The over-all sex ratio of all tagged lobsters included in this study was 52% females versus 48% males, but significantly more female lobsters were observed in the spring season than in the fall season. Assuming a normal distribution of the sex ratio among all hatched lobster eggs, and equal survival rates among female and male lobsters to market size, a 50% male, 50% female population should be available for harvest. Federal regulations require that all ovigerous females must be returned to the water, and the removal of their eggs is prohibited (Miller 1995). By protecting ovigerous females, fewer females should be landed, because on average, female lobsters will carry eggs externally for almost a year (Waddy et al. 1995), thus increasing the likelihood of catching more males at any point in time. The reason for the higher proportion of females landed in the spring season is still unclear, but could reflect a competitive behavior among males, as suggested by Campbell (1986), or perhaps a difference in the feeding behavior of male versus female lobsters.

In the early part of the Prince Edward Island fall season, a significant proportion of lobsters are in postecdysis. Because female lobsters mate shortly after the ecdysis (Talbot and Helluy 1995); a higher proportion of males caught in this period could reflect shelter-restricted behavior of females who recently molted and mated. Waddy and Aiken (1990) reported a higher relative activity of mature male lobsters than females. These behavioral differences could explain the gender ratio of landed lobsters favoring males over females observed during the fall season.

Hematology

Some hemolymph parameters have been used to define lobster health (Horney et al. 2000, Jussila et al. 1997). The range for THC and TP reported here were very large, mostly attributable to the sampling done during two different fishing seasons. In this study, 95% of the lobster population had TP levels measured on the boats were between 18.6 g/L and 99.8 g/L. The levels of TP reported by Horney et al. (2000) were within the range of these data, with mean values of 19 to 65 g/L, and the values reported by Chen and Chia (1997) in the mud crab (*Scylla serrata*) were also similar, at 81.0–88.4 g/L. Because many external factors can affect the TP and THC levels postlanding, the values obtained when lobsters were taken onto the boats were probably the most representative assessments of the natural situation. Horney et al. (2000) reported mean values for THC in their laboratory study of 6.6 to 31.1 $\times 10^6$ hemocytes/mL, while that reported by Cornick and Stewart (1978) was 18.1 $\times 10^6$ hemocytes/mL. These values are also within the mean THC ± 2 SD (95% of the population) reported in this study (5.0 to 50.5 $\times 10^6$ hemocytes/mL). Jussila et al. (1997) reported a range for THC in western rock lobster (*Panulirus cygnus*) of 2.5 to 15.9 $\times 10^6$ hemocytes/mL, with the highest mean THC in lobsters freshly arrived at the factory tanks, and suggested stress from handling or exposure to air as causative factors for the high mean of THC.

Lobster TP levels are influenced by the time of year, the molting cycle, the water temperature and probably by many other factors including diet, size, and gender (Chen and Chia 1997, Ennis 1973, Horney et al. 2000; Paterson and Spanoghe 1997). Immediately following the completion of the ecdysis, lobsters will ingest and absorb substantial volumes of seawater to expand their volume to often 50% greater than they were before the ecdysis (Aiken and Waddy 1992). This would dilute the hemolymph and result in lower TP levels and lower THC. The fall fishing season of Prince Edward Island is timed to occur after most newly molted lobsters have achieved stage C of the molting cycle, and, therefore, lower TP in the fall were expected. Chen and Chia (1997) reported the lowest protein levels for the mud crab (*Scylla serrata*) during stage B, and the highest levels during stages D_2 and D_3. High level of feeding activities could be necessary to enable lobsters to recover from the immediate low postmolt condition, as suggested by varying serum protein in field-captured lobsters (Ennis 1973).

Female lobsters had significantly higher TP levels than males at every assessed handling point of the industry during the spring season: boat, wharf, and arrival to the processing plant. Horney et al. (2000) only reported a minimal influence of sex on the different components measured in lobster hemolymph held under laboratory conditions. Chen and Chia (1997) reported no significant difference in TP levels between male and female mud crabs (*Scylla serrata*). During the fall, female lobsters had significantly higher TP levels than males only when assessed at entry to processing plants.

Another important finding was the apparent dehydration observed in lobsters kept out of the water, demonstrated by increas-

ing THC, and by TP levels to a lesser degree, from boats to wharves, and additionally from boats to arrival at processing plants. Perhaps lobsters kept out of the water for extended periods are losing considerable amounts of body fluids, resulting in hemoconcentration, and higher THC and TP values. Recently, Jussila et al. (1999) reported that only emersion periods greater than 2 hours induced significant changes in western rock lobster (*Panulirus cygnus*) THC. This correlates with the present findings, because the average emersion period calculated from the time of landing to the time of arrival at processing plants was approximately 3 hours and 15 minutes in the spring. In the fall season, this period averaged only 1 hour and 10 minutes, but because almost 82% of the fishers did not add any water at all in the live-tank after fishing, the total mean period for lobsters were kept out of the water is estimated to be at least 2 hours and 20 minutes. Dehydration has been demonstrated in prawns (*Penaeus japonicus*) to be up to 0.75% loss of body weight per hour of exposure to air, at 75–85% relative humidity (Samet et al. 1996). Newsom et al. (1994) suggested that spraying red swamp crawfish (*Procambarus clarkii*) with seawater could probably protect them against dehydration through evaporation, and may also help replace some of the body fluids lost. Jussila et al. (1999) also suggested that regular handling of lobster (*Panulirus cygnus*) as it happens during postharvest manipulation can elevate THC, and when sampling is performed during handling, especially if delays in sampling are occurring, significant elevation in THC may result after only a few minutes. It is likely that the combination of stress inflicted through increasing handling procedures from harvest time through to arrival at processing plants, and the extensive emersion periods explains the elevated THC observed at the time of arrival at the plant compared to THC estimated directly on fishing boats.

During the spring season, a significant gender difference in the THC values was seen only at the wharves, with females having higher counts. For the fall season, significant differences in THC between male and female lobsters were observed on the boats and at the time of entry into processing plants; females having higher counts than males at the plants, but lower at the boats. Overall, no consistent patterns in the THC according to sex were recorded, similar to the findings of Jussila et al. (1997) on rock lobsters (*Panulirus cygnus*). Cornick and Stewart (1978) did not assess sex differences in THC, although they looked at differential hemocyte counts and reported no significant difference according to gender. Female lobsters do not molt as often as males of comparable sizes because of the reproductive cycle, some variation between gender in both TP and THC values could be present before, during, and shortly after ecdysis, which could explain some of the results of this study.

It may be more appropriate to report TP or THC range instead of mean for indicating or predicting lobster health at the population level. The wide range of TP and THC values observed may be helpful, if certain factors affecting these ranges can be identified, and, therefore, used as indicators of health. Further studies of factors influencing the range instead of the mean values of either TP or THC are required if these factors can first be identified.

The significantly higher prevalence of *Aerococcus viridans* in lobsters from the fall fishing season compared to the spring season is likely a reflection of the warmer water temperatures in the late summer and fall. The only factor that seems to affect the prevalence of clinical disease in *A. viridans* infected lobsters is the water temperature. A decreased mean time to death with increasing water temperatures would result in increased clinical disease incidence and mortality (Bayer and Daniel 1987, Stewart 1975). Therefore, it may be possible that at higher water temperatures, more infective particles are released in the environment via decomposition of dead infected lobsters, thus increasing the likelihood of capturing live infected lobsters. Gaffkemia is a disease endemic to lobster populations of North America, and has also been reported in European waters (Alderman 1996). Huang and Bayer (1989) reported *A. viridans* prevalence of 6.7% in freshly caught lobsters off the coast of Maine. The prevalence of *A. viridans* in Atlantic Canada was estimated at almost 5% by Stewart et al. (1996), while site specific levels ranged from 0 to 22% according to Vachon et al. (1981). Keith et al. (1992) reported that 0 to 40% of lobsters caught in Canadian locations were infected with *A. viridans*. Lobsters cannot control or efficiently respond to infection with *A. viridans* (Marks et al. 1992, Stewart and Zwicker 1974). In *A. viridans* infected lobsters, there is no agglutination and the bactericidal ability of the hemolymph deteriorates in the presence of virulent strains of *A. viridans* (Johnson et al. 1981, Stewart 1975). Lobsters infected with *A. viridans* will eventually die of gaffkemia, which explains some of the confusion in the literature when reporting prevalence of *A. viridans* versus prevalence, or incidence, of gaffkemia in wild lobsters. Nevertheless, these reported infection levels agree with the prevalence estimated in this study that was 5.5% in the spring and 10.4% in the fall.

Environmental Factors

Lobsters are sensitive to freshwater exposure (Ennis 1995, Jury et al. 1994, McMahon 1995), and therefore, heavy exposure to rain will likely be detrimental to lobsters, especially for prolonged exposure times. Furthermore, exposure to sunshine could result in more rapid drying of the external surface of the lobsters, resulting in a loss of body fluids. Newsom et al. (1994) suggested that water is lost more rapidly than other components of the hemolymph, and that the hemolymph concentration should increase.

Fishing Practices

Stress from harvesting and handling of western rock lobsters has been blamed for productivity losses in the lobster (*Panulirus cygnus*) industry of Western Australia (Paterson and Spanoghe 1997). Similarities with the Canadian lobster fishery are most likely, and the various fishing practices should also have profound impacts on further industry losses. Therefore, a higher proportion of lobster injuries on boats where fishers were less careful with their catch was expected.

Setting of Traps and Bait

Cooler water temperatures at greater depths might have different impacts on lobster health than warmer waters from shallower bays. Greater changes in water temperature and hydrostatic pressure are experienced by lobsters from deeper traps when brought to the surface. Perhaps this change in pressure removes some of the oxygen from the hemocyanin, and could result in anoxia.

The type of bait, its composition, and its quality may physiologically affect lobsters postcapture. During the fall season, most fishers used two or three different types of bait, explaining why the total number of bait-types used exceeded the total number of boats (28 bait-types used by 11 boats). Bait quantity and quality has been reported to influence trap catch yields in crawfish (Romaire 1995). However, Addison and Bell (1997) reported that reduced bait attractiveness had less influence on catch rates than behavioral interactions. Unfortunately, correlations between types of bait used and numbers of lobsters caught were not investigated in this study.

Different trap attraction rates were evaluated when mussels, sea urchins, cattle hocks, animal guts, and diesel oil were used as bait in spiny lobster (*Panulirus* sp.) traps, with mussels and diesel oil being, respectively, the most effective baits (Mohan Rajan et al. 1995). Mussels as bait could represent an interesting alternative in Prince Edward Island, with the important number of mussel farms and processing plants; mussels being culled at harvest could be used in the lobster fishery. Crawfish fishers typically use "fish bait" in cold waters (< 20 °C), but when fishing in warmer waters (< 20 °C), they either use "formulated bait" or a combination of fish and formulated baits (Romaire 1995), and, therefore, a formulated bait could also represent another alternative for the fall lobster fishery.

Holding Unit and Live-Tank System

The tolerance of aquatic crustaceans to exposure to air is greatly increased by cooling the animals, and by having a high relative humidity (Samet and Nakamura 1997). Having ice in the live tank can be an advantageous alternative when no water is used. However, if the water stays stagnant for long periods, oxygen is depleted, and lobsters become hypoxic. Lobsters usually survive for longer periods if they are kept out of water, in a cool environment where their gills stay wet, compared to maintenance in stagnant water with no aeration. Keeping aquatic crustaceans dry is harmful, especially if they are exposed to wind or direct sunshine, and their gills could eventually collapse if the relative humidity drops beyond a critical value for an extended period (Samet and Nakamura 1997). The use of a lid offers some protection from direct sunlight or rain, and can help maintain the relative humidity high and constant in the live tank. The lid may also help in reducing the temperature variation inside the live-tank. Sudden and drastic changes in water temperature are stressful to lobsters, and can strongly influence their behavior (Crossin et al. 1998), and most likely their health status as well. Unfortunately, the water quality of the live-tanks was not assessed during this study and its direct effect could not be documented.

CONCLUSIONS

By tagging and following individual lobsters during the Prince Edward Island spring and fall season, lobster health was assessed at the different handling points of the fishing industry. THC and TP showed increasing levels from the time of harvest of the time of landing and subsequently, to the time of arrival at processing plants, suggesting a possible influence of handling related stress, dehydration, or possible a combination of the two. Fishing practices handling events, and lobster transportation conditions were thoroughly described. Some environmental conditions and fishing practices showed substantial variation between the spring and fall fishing seasons. Fishing conditions were warmer, sunnier, the waves were greater, and traps were set in deeper water in the fall. While fishers from both season used mainly mackerel as bait, gasperaux was only used in the spring season. In the spring season, lobsters of different sizes were prevented from having mutual contact on most boats, but only on a small proportion of boats in the fall season. Most spring fishers waited after all the traps were hauled before adding water to the live-tank compared to a majority of fall fishers who had no water in the live-tank at any time. Finally, lobsters spent on average significantly more time on board fishing vessels in the fall than in the spring season.

Attempting to follow lobsters from fishing boats through wharves and processing plants is a logistical challenge for evaluation of lobster health or productivity. In many field studies, these logistical problems have limited the ability to obtain valid results. This study enabled the investigators to identify the frequency with which a series of different fishing practices, and transportation conditions was used. Paterson (1999) suggested that analytical models could be used to predict certain outcomes, such as lobster weakness state or death from varying lobster stress indicators. By using epidemiological methods where lobster-level factors (stress indicators) and group-level factors (wharf or boat-level), a model predicting associations between factors and lobster survival would be advantageous. In a subsequent paper (Lavallée et al. 2000), the results from this study were used to build an epidemiological model assessing relationships between fishing and handling risk factors for decreased lobster vigor upon arrival at processing plants.

ACKNOWLEDGEMENTS

Special thanks to Drs. J. Davidson, G. Johnson, D. Speare, and J. VanLeeuwen for their advice and editorial comments. The authors also thank A. MacKenzie, R. MacMillan, K. Whitman, and T. Rogers for their support and help with many parts of the project, and Drs. M. Boucher, P. Campbell, A. Fraser, A. Johnson, A. Jackson, H. MacMillan, and A. Schneider for their assistance in the data collection process. This work was funded in part by the Industrial Research Assistance Program of the National Research Council of Canada, by the Canadian Atlantic Lobster Promotion Association, and by the Aquaculture & Fisheries Research Initiative of Prince Edward Island.

ABSTRACT The objective of this study was to identify risk factors for productivity losses in the Canadian lobster industry. Lobster handling and fishing practices onboard 64 fishing boats and transportation conditions on 49 vehicles subsequently transporting these lobsters from fishing wharves to processing plants were assessed during the spring and fall fishing seasons of 1997 on Prince Edward Island. These practices and conditions were then related to the health of the lobsters, estimated by the vigor status on arrival at the processing plants. A generalized estimating equation logistic regression model was used to assess the impact of handling, fishing, and transportation practices on lobster vigor. Significant risk factors for loss of vigor included the following boat-level factors: the use of mackerel for bait (odds ratio, OR, of 7.1; $P = 0.003$), tossing (as opposed to placing) lobsters from traps to temporary holding units on board the fishing boats (OR = 3.6, $P = 0.048$), and exposure to rain while on board fishing boats (OR = 3.6, $P = 0.011$), while greater maximal depths at which the traps were set had a protective effect on lobster vigor (OR = 0.85/m, $P = 0.010$).

KEY WORDS: Lobster, *Homarus americanus*, risk factors, postharvest, health

INTRODUCTION

Among Canadian fisheries, the lobster (*Homarus americanus*, H. Milne Edwards 1837) fishery is one of the most important, both in volume and in landed value. It consists primarily of a specialized inshore small boats fishery (Pringle and Burke 1993). Paterson and Spanoghe (1997) suggested that sampling lobsters at various points of handling should yield information on stressors influencing lobster health. The traditional lobster industry in Atlantic Canada is usually represented by the fishing sector that sells its daily catch to buyers located directly at the fishing ports, and these buyers can either sell their live product to processing plants or to seafood companies specializing in live holding. Lobsters can then be shipped live or processed before being exported. Variations in lobster health, before and after short or long-term holding, are hypothesized to be associated with conditions experienced while on fishing vessels and perhaps also during wharf-level handling events.

Several potential risk factors for productivity losses in the Canadian lobster industry were identified by monitoring handling and fishing practices on board fishing boats and during subsequent transport from fishing wharves to processing plants during the 1997 spring and fall fishing seasons in Prince Edward Island (Lavallée et al. 2000). These factors included some crew and boat specifications, such as crew size and years of experience of the captain. They also included the environmental variables rain, sunlight, wind, wave, water, and air temperatures. Fishing practice risk factors investigated included trap setting configuration and depth at which traps were set, lobster handling methods, type of bait, contact among lobsters before grading and banding, type of temporary storage unit and holding tank, water and lid availability for holding tanks, methods of transferring lobsters, and maximum and minimum periods spent on boats. Transportation conditions included the following risk factors: type of vehicle, presence of ice during transportation, type of shipping unit, outside air temperature, and other weather conditions, time interval between wharves and processing plants, and maximum duration shipments stayed in transport vehicles.

The objective of this study was to develop an epidemiological model to assess the impact of different fishing and handling practices previously identified as potential determinants of the health and quality of lobsters upon arrival at processing plants.

MATERIALS AND METHODS

Data Collection and Variable Selection

Data on lobster physical and physiological status, and on fishing practices, handling practices, and transportation conditions that may have a significant impact on lobster health before holding, after holding, or prior to processing and marketing were collected between May 1997 to August 1997 in Prince Edward Island, Canada. Date were obtained by monitoring fishing practices on boats and subsequent transportation conditions as lobsters were moved to processing plants. Fishing and handling practices were monitored daily in 64 groups of lobster. Each group consisted of all market-sized lobsters (carapace length ≥81 mm) caught on one boat during one day. These groups were subsequently transferred to processing plants by 49 different vehicles. Lobster health was assessed directly on board the fishing vessels, and later when

*Current address: Aquatic Science & Health Services, 158 St-Peters Road, Charlottetown, Prince Edward Island, Canada, C1A 5P8.

groups were landed, and eventually at the processing plants (see Lavallée et al. 2000 for further description of the data collection process).

Variables recorded were a mixture of continuous, ordinal, nominal, and dichotomous variables. Continuous variables were converted to dichotomous variables with two levels when the independent variable showed a tendency to group around discrete values. The outcome variable for the model was a dichotomous variable describing the vigor of each lobster upon arrival at processing plants. Every lobster was individually observed, and a lobster showing any delay or absence of response (i.e., tail flipping, claw(s) rising, antenna(e) movement) to physical stimuli was given a score of "1" (decreased vigor); whereas, a lobster showing immediate response to physical stimuli was given a score of "0" (normal vigor).

Statistical Analysis

The dataset was transferred into a statistical software package (STATA™ version 5.0, Stata Corporation, College Station, Texas, USA, 1996). After transformation of all categorical variables into dichotomous variables, 47 explanatory variables were retained. Unconditional associations between the outcome (lobster vigor score at arrival at the processing plant) and the predictors were evaluated by Chi-square tests for dichotomous variables (with corresponding relative risks) and by *t*-tests for the continuous variables. For all analyses, observed associations were considered significant when $P < 0.05$.

Variables with significant unconditional associations with the dependent variable (lobster vigor) were selected for inclusion in a multiple variable model building process. The model used was a logistic regression model using a generalized estimating equation (GEE) procedure (Liang and Zieger 1986). The model assumed a binomial error distribution, calculated robust standard errors, and used a logit link function with an exchangeable correlation structure for the correlations among lobsters within a boat.

A forward stepwise procedure under the control of the investigator (i.e., not computer generated) was used to identify variables having important associations with lobster vigor at the processing plants. Initially, a model containing only the main effect for each variable showing significant association was fit. Then, all possible two-way interactions among these individually significant variables were explored. Finally, three-way interactions were considered for inclusion in the model. Models were compared using the deviance statistic, and the model with the lowest deviance was selected. The fit of the model was assessed using a Hosmer–Lemeshow goodness-of-fit test. For comparison purposes, the final model developed using GEE was subsequently fit as a multilevel model (MLwiN Version 1, University of London) with lobster as the level 1 identifier and boat as the level 2 identifier. Second-order PQL (penalized quasilikelihood) estimates were obtained using the RIGLS (restricted iterative generalized least-squares) estimation procedure.

RESULTS

Descriptive Statistics

From 64 groups of lobsters assessed during this study, 17 groups were rejected because of missing information at the processing plants. The outcome, lobster vigor upon arrival at the processing plant, was assessed on a total of 2,191 lobsters from 47 different groups or fishing boats. Because of the limited number of boats sampled in the fall and the obvious differences in environmental characteristics, only data from 38 boats in the spring season were used in developing the model. In the spring sampling, vigor was assessed on 1,181 lobsters from 38 boats. A total of 35 lobsters had decreased vigor upon arrival at processing plants in the spring season, with 12 groups having at least 1 lobster with decreased vigor.

Measure of Association

Three continuous variables (date, maximal, and minimal depths at which traps were set) and 19 of the 39 dichotomous variables were found to be significantly associated with lobster vigor (Tables 1 and 2), and retained for further analysis. The vigor of lobsters assessed directly on boats was significantly associated with vigor upon arrival at the processing plants. However, this variable was not kept as predictor for further analysis because of the small number of cases ($n = 3$) of decreased vigor observed on boats and the plant. Similarly, flatfish as bait was also dropped; although 76 lobsters were fished with flatfish as bait, it represented only 1 fisher.

Handling and Fishing Practices

The minimal and maximal depths at which traps were set showed significant unconditional associations with lobster vigor status assessed upon arrival at processing plants (Table 1). Reduced vigor lobsters tended to come from more shallow water (minimal and maximal depths of 3.5 m and 14.8 m, respectively) compared to normal vigor lobsters (minimal and maximal depths of 5.4 m and 17.6 m, respectively).

Boats with smaller crews and older captains tended to have a higher risk of producing low vigor lobsters (Table 2). Lobsters landed from boats with crews of two or fewer members were 2.4 times more at risk of having a decreased vigor at the processing plant than lobsters landed by larger crews, while the same risk was 3.0 times greater when landed by a captain with more than 20 years of experience compared to less experienced captains.

A number of weather-related variables had significant unconditional associations with lobster vigor (see Table 2). Warm weather, rain, sunlight, and rough weather (waves) all increased the risk of low vigor. After dichotomization, both the maximum (>10 °C or ≤10 °C) and minimum (>9 °C or ≤9 °C) air temperatures had significant unconditional associations with lobster vigor at processing plants. When the maximum temperature was above 10 °C, lobsters were 3.6 times more likely to experience loss of vigor at the plants than when the maximum daily temperature was 10 °C or below. A similar situation was noted with the minimal daily air temperature, with relative risk of observing decreased lobster vigor at the plant of 3.1 when the minimal air temperature was above 9 °C. When caught on rainy days, lobsters were 6.3 times more likely to have decreased vigor upon arrival at the plant compared to nonrainy days. Also significant was the exposure to sunlight, with relative risk for lobster decrease in vigor of 5.3 if landed on sunny days as compared to cloudy days. When the waves were classified as moderate to strong, lobsters were 3.3 times more likely to suffer from loss of vigor at the plants compared to when waves were calm to minimal.

Boats fishing with mackerel or flatfish baits were at higher risk of delivering lobsters with lower vigor; whereas, boats fishing with gaspereaux bait landed livelier lobsters (Table 2). When fished

TABLE 1.

Unconditional associations between fishing practices and lobster (*Homarus americanus*) characteristics that were measured on a continuous scale, and a measure of lobster vigor at the processing plant.

Variable	Description	*P*-value	Mean	
			Normal vigor[1]	Decreased vigor[1]
Date	Date of the boat sampling (# of days from January 1)	0.026	162.9	166.3
Water temp.	Surface water temperature (°C)	0.181	7.9	8.6
No. traps	Number of traps hauled	0.111	289	300
Max. depth	Maximum depth at which the traps were set (m)	0.001	17.6	14.9
Min. depth	Minimum depth at which the traps were set (m)	0.003	5.4	3.5
Weight	Individual weight as measured at the wharf (kg)	0.381	0.58	0.63
Length	Individual carapace length as measured on the boat (mm)	0.414	88.2	89.4
Protein	Total hemolymph protein, on the boat (g/L)	0.190	77.4	84.8
Hemocyte	Total hemocyte counts, on the boat ($\times 10^6$ hemocytes/ml)	0.422	198.3	221.3

[1] Normal and decreased vigor as assessed at the processing plant with the dichotomous variable "vigor."
The *P*-values were obtained by *t*-test.

with mackerel, lobsters were almost 4 times more likely to express loss of vigor compared to fishing with alternate baits, while gaspereaux had a protective effect whereby lobsters fished with gaspereaux were only one-third as likely to have reduced vigor. Lobsters fished with flatfish as bait seemed to be 5.3 times more likely to suffer loss of vigor upon arrival at the processing plant. However, flatfish bait was used by only one fishing boat included in the study and, therefore, its unconditional effect may be overestimated. For a complete description of the frequency distribution of the baits used see Lavallée et al. (2000).

Rough handling, physical contact among lobsters before measuring the carapace, the use of plastic totes as temporary storage units, and packing lobsters over at the wharves, were all practices that induced higher risk for loss of lobster vigor (Table 2). Lobsters coming from boats where physical contact before carapace measurements was possible had an 18 times greater chance of suffering loss of vigor at the processing plants than if they were landed from boats in which physical contact between lobsters was purposefully prevented. Lobsters landed from boats in which lobsters were generally tossed from the traps to the temporary holding units were almost 3 times more likely to suffer vigor loss at plants as compared to lobsters that were placed into temporary holding units. If these temporary holding units were the traditional plastic totes, then lobsters were 4 times more likely to express loss of vigor at processing plants than if other types of temporary storage units were used (Table 2). Furthermore, the practice of packing over the lobsters once at the wharf showed that lobsters that went through this process were more than 3 times more likely to have decreased vigor at the processing plants than lobsters that did not go through this process. All other handling and fishing practices did not show any significant unconditional association with the lobster vigor status at processing plants (Table 2).

Transportation Conditions

Three transportation variables individually showed statistically significant association with lobster vigor loss when assessed at arrival at processing plants: the use of closed compartment vehicles, warmer outside air temperatures, and windy conditions during transport between wharves and processing plants (Table 2). When the transport vehicle was a nonrefrigerated closed compartment truck, lobsters were almost four times more likely to have decreased vigor than if other types of vehicles (open-bed truck or pick-up truck, and vehicle equipped with a closed refrigerated transportation) were used. In the presence of moderate to strong winds during transportation, the proportion of lobsters that suffered from loss of vigor upon arrival at the processing plants was 7.3% as compared to 1.5% in the presence of calm or light winds; lobsters transported during windier days were more than five times more likely to have vigor loss at the plants. Finally, if the outside air temperature was above 18 °C, lobsters became seven times more likely to suffer vigor loss at the processing plants than if the air temperature was 18 °C or less. No other transportation conditions showed significant association with lobster vigor at the processing plants.

Regression Models

The Generalized Estimating Equation logistic regression model (GEE) identified four significant variables predicting lobster vigor at the processing plant: maximum depth at which traps were set, occurrence of rain during fishing, tossing of the lobsters from traps to temporary storage units, and the use of mackerel as bait (Table 3). While controlling for other factors, lobsters landed from boats in which mackerel bait was used instead of alternate baits were 7.1 times more likely to have decreased vigor at the processing plants; lobsters were 6.3 times more likely to have decreased vigor if landed on rainy days as compared to nonrainy days; and lobsters from boats on which they were generally tossed into the temporary holding units were 3.6 times more likely to experience vigor loss at the plant. Finally, lobsters caught in deeper waters were less likely to have loss of vigor at the processing plants than lobsters caught from shallower waters, with the risk of experiencing loss of vigor decreasing by 1.2 for every meter increase in depth, while controlling for other variables in the model.

The deviance for the multivariable model was 240.81, the Pearson dispersion coefficient for the model was 1.03, with a total of 1,148 observations, and the Chi-square value for the over-all significance of the model was 36.56 ($P < 0.001$). The standard errors were adjusted for clustering on the boat, using the GEE model. The Hosmer–Lemeshow goodness-of-fit test yielded a Chi-square value of 8.11 with a *P*-value of 0.423 (critical value = 15.507, *P*

[1] Outcome.
The *P*-values were obtained by Chi-square tests.
RR is the relative risk associated with each variable.

≤ 0.05, $df = 8$). Therefore, it was concluded that the model was a reasonable fit for the data.

All parameter estimates from the multilevel model (results not shown) were virtually identical to those obtained from the GEE procedure. In addition, the level two (boat) variance was zero once the fixed effects in the model had been accounted for. This indicates that once the variables maximum depth at which traps were set, occurrence of rain during fishing, tossing of the lobsters from traps to temporary storage units, and the use of mackerel as bait were controlled, the probability of reduced vigor was essentially independent of the boats.

DISCUSSION

It is important to understand the difference between causation and association. A risk factor is associated with the outcome when the distribution of the outcome is significantly different between the "exposed" and "nonexposed" (Martin et al. 1987); whereas, causation must additionally include a set of guidelines to assess the likelihood of the association to be causal. Among these guidelines (but not limited to) are the following: the exposure to the risk factor must precede the outcome; the exposure to the risk factors should also be more common in the individuals expressing the outcome than in those individuals without the outcome; the removal of the risk factor should decrease the incidence of the outcome; and, the modification of the host's response should also decrease the incidence of the outcome (see Evans 1978 for a complete description of these guidelines).

Some correlation among the variables in the GEE model was present. This explains the multicollinearity problems encountered during the model building process, especially among dummy variables. Multicollinearity concerns relationships among predictor variables, but does not directly involve the outcome (Kleinbaum et al. 1988), and GEE models do not take multicollinearity problems into account. When a predictor is included in the model, adding another predictor that is correlated to the previous one contributes relatively little to the explanatory model and would seem to be nonsignificant. Care was taken during the model-building process to avoid this.

GEE models are more efficient if variables are independent (Liang and Zeger 1986). Although lobster-level predictors were clustered within fishing boats, GEE models account for factors up to two levels of clustering (Pendergast et al. 1996). However, this study did not result in any lobster-level predictors remaining in the final model.

More than 45% of all potential determinants measured showed significant crude association with the outcome, loss of vigor. Having multiple observations for every cluster; that is, multiple lobsters per fishing boat, can artificially increase the significance of many determinants (Kleinbaum et al. 1988), and a conservative approach must be taken when drawing conclusions, especially with crude associations. Although the distribution of the event of con-

Max depth	0.85	−3.008	0.003	−0.085	−0.018
Rain	3.63	2.538	0.011	0.294	2.286
Handling	0.28	−1.977	0.048	−2.559	−0.011
Mackerel	7.07	3.018	0.003	0.686	3.226

Max depth: maximum depth at which the traps were set (m).
Rain: if it was raining during fishing.
Handling: if the lobsters were placed (versus tossed) from the traps to the temporary storage unit.
Mackerel: if fresh mackerel was used as bait.

cern was binomial and took on only one of two values (normal or decreased vigor), the frequency of the event meant that the number of boats with decreased lobster vigor was sufficiently rare to have little statistical power if the data had been collapsed to the boat level. Because the data were clustered at the boat-level, an ordinary logistic regression would not account for this clustering (Kleinbaum et al. 1988), and would likely overestimate the significance of predictor variables. The investigators wanted to keep individual lobsters as the unit of evaluation, so both lobster-level and boat-level factors could be considered. Consequently, a GEE logistic modeling approach was chosen.

The final GEE model included four significant predictors. The significant predictors for loss of vigor at arrival at processing plants did not include any lobster-level factors, but only consisted of boat-level factors. Lobsters landed from boats using mackerel bait were more than seven times more likely to suffer from loss of vigor when arriving at the processing plant as compared to lobsters landed from boats using alternative baits, when controlling for the other variables. The biological or physiological explanation for this phenomenon is unclear. Scombroid fish, such as mackerel, contain high levels of the amino acid histidine (Nemetz and Shotts 1993). Decomposition of such fish, which is more likely to occur when carcasses are not refrigerated for extended periods, produces significant amounts of histamine by bacterial decarboxylation of the histidine (Barancin et al. 1998). Bacterial histamine contamination has been associated with adverse health effects when scombroids are consumed directly by humans (Barancin et al. 1998). If histamine is present in lobster baits, it could possibly adversely affect the health of harvested lobsters. Mackerel were not tested for histamine levels in this study, and, therefore, this is speculation without any real evidence. Further investigation of the effect of mackerel with different states of decomposition and histamine levels on lobster health would be necessary before this speculated link could be seriously considered. More recently, Castonguay et al. (1997) demonstrated the presence of small amounts of paralytic shellfish poisoning (PSP) toxins in the Atlantic mackerel. Perhaps the slight accumulation in mackerel of toxins related to paralytic shellfish poisoning may influence lobster health. It is also possible that mackerel can influence lobster health for other reasons.

Using less care in the over-all handling process of lobsters on board the boats is likely to result in loss of vigor. Tossing lobsters made them 2.9 times more likely to have loss of vigor at the processing plant than lobsters placed into the temporary storage unit, when the effect of other variables was controlled.

Groups of lobsters landed on rainy days were 6.3 times more likely to lose vigor compared to landings on days without rain. Lobsters are sensitive to fresh water exposure (Jury et al. 1994, Ennis 1995, McMahon 1995), and heavy exposure to rain will likely be detrimental for lobsters, especially for prolonged exposure times.

The odds ratio for the maximum depth at which traps were set was 0.85 for each meter. For each 3 m of additional depth at which traps were set, the lobsters became approximately 1.6 times less likely to suffer from loss of vigor upon their arrival at processing plants. Colder water temperatures found at greater depths are perhaps closer to those preferred by lobster (Crossin et al. 1998), and thus may have beneficial impacts on lobster vigor. Also, Lawton and Lavalli (1995) reported that lobsters may occasionally experience hypoxia in warm waters, especially in intertidal environments. Because of their aggressive and territorial behaviour (Aiken and Waddy 1995), perhaps some lobsters were forced to move toward less optimal habitats resulting in a precapture bias toward less healthy lobsters when caught in more shallow waters.

Lobster health predictors at the group-level (i.e., boat-level) would probably be more accessible to the industry, because they would not require individual assessments of lobsters. However, predictors at the individual (i.e., lobster-level) should yield more accurate estimates of population health, assuming a valid sample that is representative of the wild populations. None of the lobster-level parameters assessed in this study proved to be good predictors of lobster health at the processing plant, as assessed by the vigor state. Other lobster level predictors, such as physiological parameters, should be assessed to help define lobster health. The quantification of the Crustacean Hyperglycaemic Hormone (CHH) being correlated with stress levels in some decapods including the American lobster, may have potential (Chang et al. 1998, Paterson and Spanoghe 1997). Inorganic ions, such as magnesium, calcium, or potassium, metabolites and waste products such as glucose concentration and ammonia levels in the hemolymph should also be considered for further research, as proposed by Paterson and Spanoghe (1997). Although total hemolymph protein (TP) is used as a lobster health predictor by the industry, these data did not indicate that individual lobster vigor upon arrival at the processing plants was predicted by TP measurements. No association was found between low TP levels and decreased vigor at processing plants.

Perhaps the lack of correlation between the physiological parameters used in this study and the vigor state of lobsters at the processing plants was because of the lack of statistical power, with only 35 lobsters with decreased vigor in the dataset. Although the internal validity of these results is acceptable, it may not be valid for lobster health and fishing practices outside of Prince Edward Island. The lack of correlation with the outcome may also be partly explained by the utilization of a subjective outcome (lobster vigor) not sensitive enough to detect lobster stress, or loss of liveliness. Recently, Paterson (1999) suggested that analytical models may be useful in predicting certain outcomes, such as lobster weakness state or even lobster death. Epidemiological models using survival analysis methods to correlate lobster-level, boat-level, or transport-level parameters to lobster survival poststorage may be very informative, but are not appropriate for Prince Edward Island. Live lobster holding is rarely for more than 10–14 days in Prince Edward Island, and, therefore, the frequency of reduced lobster survival would probably not be sufficiently high to justify using survival models.

CONCLUSION

The main objective of this study was to establish an epidemiological model assessing the impact of different transportation, fishing, and handling practices on the health and quality of lobsters upon arrival at processing plants. Four lobster health predictors were identified, although no transportation condition factors were significantly associated. The use of different baits influenced lobster vigor with mackerel being detrimental. Further investigations of the types and quality of bait used and its influence on lobster health should be conducted. Lobster fishers should be encouraged not to toss lobsters, because gentle handling seems to enhance lobster vigor. Protection from rainy weather conditions should reduce industry losses, because lobsters directly exposed to rain experienced vigor loss. Setting lobster traps in deeper waters also seemed to be beneficial to lobster health. However, changing the water depth of traps is not readily altered by fishers because of

many other uncontrollable influences on areas available for fishing. When building such epidemiological models, it is always possible that there may be unmeasured or unmeasurable factors that are more related to the outcome (in this case, loss of vigor upon arrival at the processing plants), or that were indirectly measured with the factors included in the model-building process.

Lobsters caught in Prince Edward Island generally experience very low mortality rates preprocessing. Therefore, an examination of factors associated with survival was not feasible in Prince Edward Island. This low level of mortality is likely a result of several factors; most canner-sized lobsters (approximately 63.5–81 mm) are held in pounds for extremely short periods, and the majority of lobsters caught in Prince Edward Island waters are canner-sized lobsters. To examine handling factors on the boat and their association with survival, a similar evaluation should occur in other areas of Atlantic Canada where market-sized lobsters and weak lobsters may exist in greater proportions and where they are held in captivity for longer periods.

FORAGING BEHAVIOR OF *CARCINUS MAENAS* (L.): COMPARISONS OF SIZE-SELECTIVE PREDATION ON FOUR SPECIES OF BIVALVE PREY

M. MASCARÓ* AND R. SEED

ABSTRACT Experiments were designed to investigate size-selective predation by medium (40–55 mm carapace width) and large (55–70 mm) *Carcinus maenas* when feeding on four bivalves of contrasting shell morphologies, mussel, *Mytilus edulis*, flat oyster *Ostrea edulis*, Pacific oyster *Crassostrea gigas*, and edible cockle *Cerastoderma edule*. Medium-sized crabs preferred mussels 5–15 mm shell length (maximum shell dimension) and cockles 5–10 mm long, whereas large crabs preferred mussels 15–25 mm and cockles 10–20 mm long. Generally, no preference was shown for any particular size of either species of oyster. Comparisons amongst the preferred size ranges of prey showed that crab preference for a particular size range of prey was more strongly related to the minimum than to the maximum shell dimension, and that the minimum shell dimension was always equivalent to, or smaller than, the maximum cross section of the crabs' chelae. The size ranges of *M. edulis* and *C. edule* selected by *C. maenas* either clearly corresponded to, or were slightly smaller than, the size ranges of prey with the highest profitability (= dry weight consumed per unit of handling time). Profitability values of *M. edulis* and *C. edule*, however, showed considerable scatter; whereas those of *O. edulis* and *C. gigas* were even more variable. This variation seems to be the result of behavioral strategies by which crabs attack all encountered prey but reject those that remain unbroken after a certain number of opening attempts. Our results emphasize the mechanistic nature of size-selective feeding in *C. maenas*, and suggest that the differences in the observed patterns of size-selection were mainly determined by the contrasting morphological features of the bivalve shells, and the way these features influence the vulnerability of prey to crab predation.

KEY WORDS: Foraging behavior, *Carcinus maenas*, size-selection, bivalve

INTRODUCTION

Behavioral and mechanical aspects of predation by crabs that forage extensively on bivalve populations have been recurrent topics in research (e.g., Blundon and Kennedy 1982, Hughes and Seed 1995, Seed and Hughes 1995). Selective foraging is a major aspect within this topic, given the direct influence that the removal of certain prey types has on the abundance and distribution of the populations involved in the predatory interaction and of other species in the system that are related to them (Ebling *et al.* 1964). Many authors studying crab selective foraging behavior have related their findings to the Optimum Foraging Theorem, whereby a predator chooses its diet to maximize net energy intake per unit of handling time (Charnov 1976, Hughes 1980). Given a choice of different sizes and species of prey, a predator should select that with the highest dietary value (Pyke *et al.* 1977). However, minimisation of handling time (Hughes and Seed 1981) and the risk of claw damage associated with attacks on larger, more resistant prey items (Juanes 1992) have also been suggested as causal factors of prey selection in several crab–mollusk predator–prey relationships.

Because handling times, and, hence, prey values, have a complex variation related to the morphological characteristics of the crab chelae and the prey shell, foraging tactics can vary when crabs feed on different species of prey (Creswell and McLay 1990). Moreover, foraging strategies can also be related to differences in the patterns of prey dispersion that crabs encounter in their natural habitats (Hughes and Elner 1979). Thus, comparisons of foraging behavior when crabs are presented with different hard shelled prey can provide enlightening information regarding the basis of prey selection. Whereas numerous studies have addressed the dietary and energetic consequences of selective feeding (reviewed by Hughes 1990), few have identified the cues that make such foraging behavior possible (e.g., Kaiser *et al.* 1993).

The shore-crab, *Carcinus maenas* (L.), is abundantly distributed in the North Atlantic and is particularly common around the British Isles (Ingle 1980). Predation by shore-crabs can influence the abundance and distribution of commercially important bivalves when these are an integral part of the crab's natural diet (e.g., Dare *et al.* 1983; Sanchez-Salazar *et al.* 1987a). We investigated the foraging behavior of adult *C. maenas* when feeding on four species of bivalve mollusks with contrasting shell morphologies: the mussel, *Mytilus edulis* L.; the flat oyster, *Ostrea edulis* L.; the Pacific oyster, *Crassostrea gigas* (Thunberg); and the cockle, *Cerastoderma edule* (L). Comparisons amongst the foraging strategies adopted when feeding on these species are used to identify the stimuli involved in prey selection and to determine the basis of their size-selective feeding behavior.

MATERIALS AND METHODS

Samples of intertidal *Mytilus edulis* and *Cerastoderma edule*, covering as wide a size range as possible, were collected from naturally occurring populations at various sites around the Isle of Anglesey, North Wales. Samples of *Ostrea edulis* and *Crassostrea gigas* were obtained from CEFAS commercial oyster beds located in the Menai Strait in North Wales. Shells were cleaned of any attached fouling organisms and shell length (SL: maximum linear dimension of the shell), shell height (SH: maximum linear dimension of the axis at right angles to SL), and shell width (SW: minimum linear dimension of the shell) of each individual were measured to the nearest 0.1 mm using vernier calipers. Soft tissues were removed following brief immersion in boiling water and dried to constant weight at 60 °C. Dry tissue weight (W) was then determined to the nearest 0.01 mg on a top loading balance. Re-

lationships between shell length (x) and width, height, and dry weight (y) were best described by the allometric equation $y = a \cdot x^b$ where a & b are constants. Linear relationships amongst these variables were obtained by least-square regressions on logarithmically transformed data. Regression lines were compared by analysis of variance using the General Linear Model with shell length as the covariate. Pairwise comparisons between the regression slopes and intercepts were then performed using Tukey's method.

Carcinus maenas 40–70 mm carapace width (CW) were collected by hand from the low shore in the Menai Strait, and maintained individually in plastic aquaria (30 × 20 cm) filled to a depth of 10 cm with running sea water. Water temperature in the aquaria varied between 12–17° C, and photoperiod was kept constant at approximately 14 h light: 10 h dark using 40 W fluorescent lights. Only undamaged male crabs in the later intermoult stage were used in the experiments in order to avoid any potential bias caused by morphological and behavioral differences associated with sex and moult stage. Following their capture, crabs were starved for 48 h before experiments in order to standardize hunger levels. Size-selection experiments were carried out by presenting medium-sized (40–55 mm CW) and large (55–70 mm CW) crabs with prey species ranging from 5–40 mm SL. Only one species of prey was offered to the crabs during any single feeding experiment. Each crab was simultaneously offered five prey items in each 5-mm size class. Prey items were scattered randomly over the floor of the aquaria and monitored twice a day. Any item consumed within each 12 h period was recorded and replaced by another of similar size in order to maintain constant prey availability. Experiments were run continuously until a consistent feeding pattern emerged (≈10 d).

The number of prey consumed within the different size classes was analyzed using a chi-square test to determine whether these deviated from random choice (Peterson and Renaud 1989). Because the number of size classes of prey offered to crabs was never less than five, in the event of chi-square tests being significant, the preferred size classes would be those consumed in >20% of the total number of prey consumed. Comparisons of the size ranges of prey preferred by both size categories of crabs were made on the basis of: (1) shell length; (2) width; and (3) relative prey size, which was obtained by dividing the median value of shell width within each of the size classes of each prey species offered by the height (maximum cross section) of the major chela. The height of the major chela in *C. maenas* was estimated using the allometric equation $MH = 0.13\ CW^{1.21}$ ($r^2 = 0.98$; $n = 61$) where MH (mm) is master chelal height and CW (mm) is carapace width (Mascaró, 1998). To compare the biomass corresponding to the total number of items of each prey species that were consumed daily by each crab, the dry flesh weight (mg) of the ingested prey within each size class was estimated from the median lengths of each size class using the appropriate allometric equations.

Handling time experiments were carried out by offering each medium-sized and large crab a prey item of known shell length, and recording: (1) breaking time (Tb), the time from the first physical contact with the prey item, through the period of manipulation to the point where the shell was finally opened and the flesh exposed; (2) eating time (Te), the period from when the prey was opened to the point where the meal was completed and the empty shell abandoned; and (3) handling time (Th; i.e., the sum of Tb and Te). If the crab was successful in the attack, another prey item was presented, and this procedure repeated until data for a wide size range of prey were obtained. If crabs were reluctant to eat, they were starved for 1–3 days until hunger levels recovered. Least-squares regressions on previously log-transformed handling times were fitted to the exponential model $y = a \cdot e^{xb}$ where a and b are constants, and handling time curves were predicted for each crab using parameters a and b. Prey profitability was estimated as dry flesh weight per unit of observed handling time (mg · sec^{-1}). Profitability curves were, therefore, obtained by dividing the estimated dry flesh weight of a prey item of known shell length by the handling time predicted by the exponential model. Analysis of variance (ANOVA) and Scheffe's method for pairwise comparisons of breaking times and profitability values between prey spe-

Coefficients a (intercept) and b (slope) in the linear model ($\log y = \log a + b \log x$) were obtained by least square regressions; r^2 is the coefficient of determination. Results of Tukey's pairwise comparison tests performed on the regression coefficients (slopes: normal type; intercepts: bold type) of each allometric relationship are also presented: $^*P < 0.05$, ns = not significantly different.

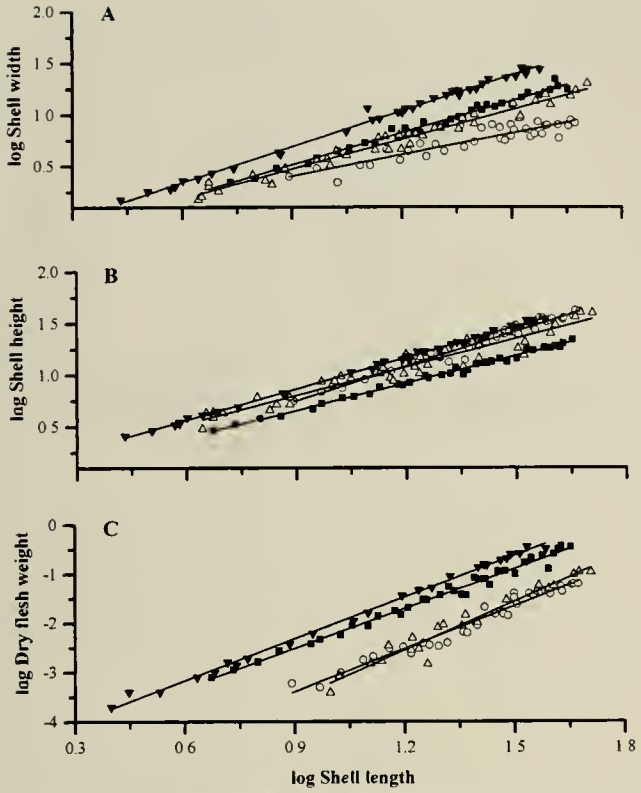

Figure 1. Relationships between (A) shell width (mm), (B) shell height (mm), (C) dry flesh weight (mg) and shell length (mm) for a wide size range of *Mytilus edulis* (solid squares), *Ostrea edulis* (open circles), *Crassostrea gigas* (open triangles), and *Cerastoderma edule* (solid triangles). Solid lines represent predicted values based on the parameters of the allometric equations presented in Table 1.

cies were performed on the basis of the size ranges of prey preferred by crabs during the size-selection experiments. In those cases where crabs exhibited no apparent size preference, the size range used was comparable to that for the preferred size range of mussels. Breaking times and profitability values were log-transformed before analysis of variance was applied to the data.

RESULTS

Analysis of variance of the allometric relationships between shell length and shell width, height and dry flesh weight revealed significant differences amongst the four bivalve species (Table 1). Analysis of variance showed significant differences amongst the slopes ($F = 34.12$; $P < 0.001$) and intercepts ($F = 2.87$; $P < 0.05$) for the regressions between shell width and length of the four species examined (Table 1). With increase in shell length, *C. edule* increased in shell width more rapidly than *M. edulis* and *C. gigas*, which in turn increased in shell width more rapidly than *O. edulis*. Analysis of variance on the regression lines of shell height and length showed significant differences amongst the slopes ($F = 11.5$; $P < 0.001$) and intercepts ($F = 6.88$; $P < 0.001$). With increase in shell length, *O. edulis* increased in shell height more rapidly than *C. edule*, which, in turn, increased more rapidly than *M. edulis* and *C. gigas*. Thus, among small individuals shell width and height of the four bivalves were broadly similar. However, among larger prey, *C. edule* had a significantly wider shell than both *M. edulis* and *C. gigas* of comparable shell length; whereas, *O. edulis* had the narrowest shell of the four species (Fig. 1A). Large *O. edulis* and *C. edule*, however, had significantly higher shells than both *M. edulis* and *C. gigas* of comparable length (Fig. 1B).

Results of the analysis of variance on the regression lines of weight and shell length showed significant differences among the slopes ($F = 6.82$; $P < 0.001$) and intercepts ($F = 46.92$; $P < 0.001$). Pairwise comparisons between regression parameters revealed that the regression lines for *M. edulis* and *C. edule* are not significantly different from each other (Table 1), and that both have the same slope but a higher elevation than the regression line for *O. edulis*. These results suggest that both *M. edulis* and *C. edule* had significantly more biomass than any *O. edulis* of comparable shell length (Fig. 1C). The regression line for *C. gigas* intersects that for *O. edulis*, suggesting that among smaller prey, Pacific oysters had less biomass than mussels, cockles, and flat oysters. However, with increase in size, the biomass of *C. gigas* increased more rapidly than in the other species (slope: 3.30 ± 0.34) so that among prey > 20 mm long, *C. gigas* had more flesh than *O. edulis* of comparable shell length.

Both the degree of crab selectivity (i.e., pattern of size selection) and the maximum length of prey consumed by *C. maenas* varied from one prey species to another (Fig. 2). Although the percentage of mussels consumed by all crabs decreased slowly among mussels of increasing shell length, the percentage of cockles consumed declined steeply among the larger size classes of prey. The maximum shell length of *M. edulis* opened by medium-

(A) Number (± se) and (B) percentage of *Mytilus edulis*, *Ostrea edulis*, *Crassostrea gigas*, and *Cerastoderma edule* that were consumed daily by each *Carcinus maenas* 40–55 mm CW (black columns) and 55–70 mm CW (hatched columns) during a period of 8–10 days. Note that *C. gigas* 5–10 mm in shell length were not available during these experiments (nd = no data).

TABLE 2.

Results of chi-square (χ^2) tests on the total number of prey consumed by medium (40–55 mm CW) and large (55–70 mm CW) *Carcinus maenas* during size-selection experiments.

	Medium				Large			
		Preferred Size Ranges				Preferred Size Ranges		
Species	χ^2	SL	SW	RPS	χ^2	SL	SW	RPS
M. edulis	699.5*	5–15	2.0–6.3	0.15–0.46	235.9*	15–25	6.3–10.6	0.33–0.56
O. edulis	7.2 ns	——	——	——	4.0 ns	——	——	——
C. gigas	22.8*	10–15	3.7–5.4	0.27–0.40	3.1 ns	——	——	——
C. edule	282.6*	5–10	2.9–6.4	0.21–0.47	165.1*	10–20	6.4–14.1	0.34–0.75

RPS was calculated as the median value of shell width in each size class of prey divided by the height of the master chela in each size category of crab. The preferred (i.e., consumed in >20%) size ranges of each prey species are expressed in terms of shell length (SL mm), shell width (SW mm) and relative prey size (RPS) when chi-square tests proved statistical significance; *significant at $P < 0.001$, ns = no significant departure from a random choice.

sized and large crabs was 20–25 and 35–40 mm, respectively; whereas, the maximum shell length of *C. edule* opened by both size categories of crabs was 20–25 mm. By contrast, crabs included *O. edulis* and *C. gigas* of up to 35–40 mm in their diet and were less size selective than when feeding on mussels and cockles, resulting in relatively more uniform distributions in both oyster species.

Chi-square analysis on the number of prey consumed by each size category of crab revealed that medium-sized crabs (40–55 mm CW) significantly preferred mussels of the two smallest size classes (5–15 mm SL), and cockles of the smallest size class offered (5–10 mm SL; Table 2). Larger crabs (55–70 mm CW) showed a significant preference for slightly larger mussels (15–25 mm SL) and cockles (10–20 mm SL). Neither medium nor large crabs included cockles >25 mm long in their diets. When feeding on oysters, crabs generally showed no preference for any particular size class of either species, the only exception being medium-sized *C. maenas* that consumed *C. gigas* 10–15 mm long in significantly higher numbers, but included Pacific oysters of all size classes offered. Differences between the preferred size ranges of prey were larger when expressed in terms of shell length than in terms of shell width. For example, medium *C. maenas* preferred mussels 5–15 mm and cockles 5–10 mm long, but these measured 2.0–6.3 mm and 2.9–6.4 mm in shell width, respectively. In addition, crabs always preferred prey with a relative prey size <1, suggesting that preferred prey was always smaller than the height of the largest chela.

The total number of each prey species consumed daily by each size category of crab and the corresponding biomass (mg) varied from one prey species to another (Table 3). *Carcinus maenas* consumed more mussel flesh than any of the other bivalves offered, and differences in consumed biomass were greatest between *M. edulis* and *O. edulis*. There was a general trend toward higher biomass consumption among crabs 55–70 mm CW, but these larger crabs generally consumed fewer prey items than crabs 40–55 mm CW, presumably because large crabs fed on larger prey and these would have proportionately greater biomass.

Handling times and profitability curves for each size category of crab feeding on each prey species and the estimated parameters of the exponential relationships varied among the four bivalve prey (Table 4, Fig. 3. The strong reluctance of *C. maenas* to feed on large *C. edule* did not allow for handling curves to be predicted for cockles >20 mm long. However, handling times for small cockles were overall much lower than for any of the other prey species. From the handling time data it is clear that large crabs required less time to handle prey of any particular shell length than did medium-sized crabs, and, consequently, had access to larger prey items of any of these prey species. Results showed a considerable scatter within the handling time data for each prey species, and this became more extreme when profitability values were plotted, particularly among crabs feeding on *O. edulis* and *C. gigas*. Nonetheless, profitability plots suggest that larger crabs were consistently capable of obtaining higher profitability than medium-sized crabs, regardless of the size and species of prey offered. There also seemed to be an optimum size of prey, below and above which

a and b were estimated as: ln Th = ln a + b SL; r^2 is the coefficient of determination.

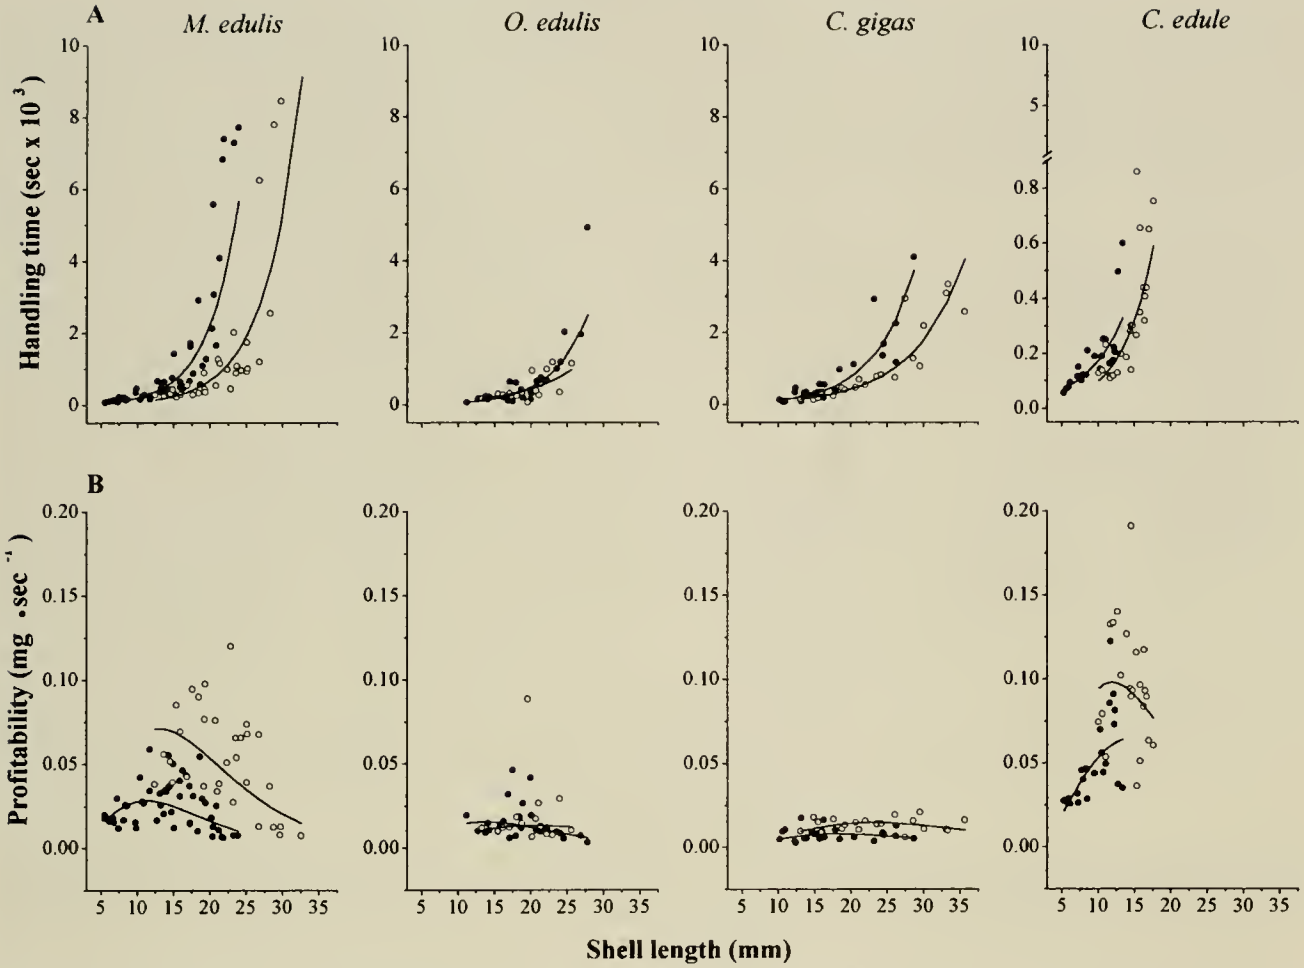

Figure 3. (A) Handling time and (B) profitability for a size range of *Mytilus edulis*, *Ostrea edulis*, *Crassostrea gigas*, and *Cerastoderma edule* consumed by *Carcinus maenas* 40–55 mm CW (solid symbols) and 55–70 mm CW (open symbols). Solid lines represent predicted values based on the parameters of the exponential equations presented in Table 4, and on the dry weight-shell length relationships presented in Table 1. Note scale change for *C. edule* handling time.

profitability decreased, and this optimal size seemed to increase as a function of crab size. In both oyster species, however, the size range at which profitability was maximized was wide, and peaks were relatively broad. Both medium and large *C. maenas* obtained slightly higher profitability when feeding on cockles than on mussels of similar shell length, and crabs would, therefore, need to feed on slightly larger mussels than cockles to obtain similar profitability.

The ranking order of prey profitability paralleled the order in which prey were consumed by both size categories of crabs during feeding experiments (Fig. 4). Analysis of variance showed that profitability of the preferred size range of *M. edulis* was significantly greater than that of *O. edulis* and *C. gigas* (Table 5). The preferred size ranges of mussels and cockles, however, provided similar profitability for crabs in both size categories. No significant differences were detected between profitability of the preferred size classes of *O. edulis* and *C. gigas* for either medium or large crabs. Analysis of variance of breaking time of the preferred size range of each prey species revealed that medium-sized crabs took significantly less time to break open cockles than mussels of the preferred size range (Table 5). Among large crabs, however, significant differences were only found between prey with extreme values (*C. gigas* > *C. edule*). No significant differences were ever found between the breaking times of mussels and oysters or between the two oyster species. Because crabs generally took similar times to open all four bivalves, these results suggest that differences in profitability between the selected size ranges of prey were mainly because of differences in their biomass.

DISCUSSION

Optimal Foraging Theory assumes that predators are able to rank prey in the order of their dietary value, and predicts that prey should be selected accordingly (Charnov 1976, Pyke *et al.* 1977, Hughes 1980). When, in the present study, *Carcinus maenas* were fed *Mytilus edulis* and *Cerastoderma edule*, there was an optimum size range of prey above and below which profitability (= dry flesh weight ingested per unit of handling time) decreased (Fig. 3). Moreover, the size ranges of *M. edulis* and *C. edule* actually selected by these crabs either closely corresponded to, or were slightly smaller than, the size ranges of prey with the highest profitability (Table 2). Results similar to these have previously been demonstrated for *C. maenas* when feeding on mussels (Elner and Hughes 1978) and cockles (Sanchez-Salazar *et al.* 1987b).

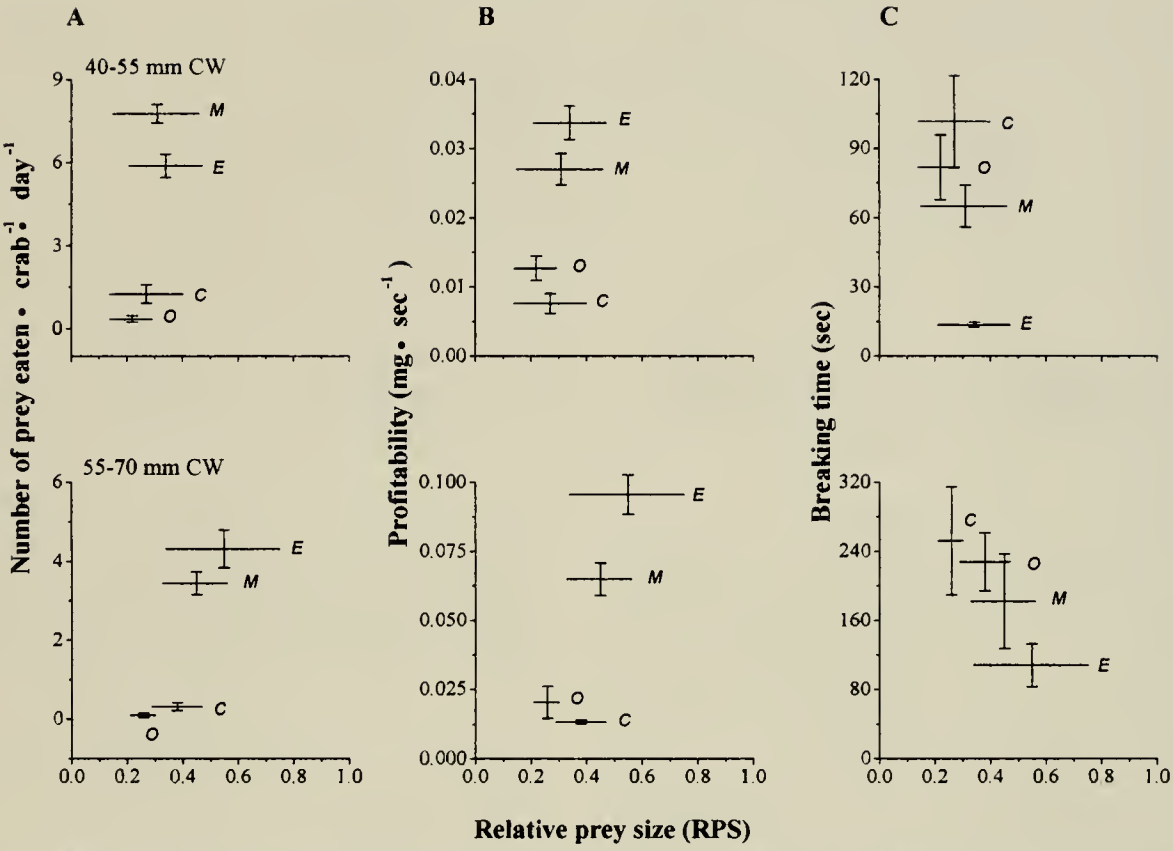

Figure 4. (A) Mean number (± se), (B) profitability (± se) and (C) breaking time (± se) of *Mytilus edulis* (*M*), *Ostrea edulis* (*O*), *Crassostrea gigas* (*C*), and *Cerastoderma edule* (*E*) of the size range that were preferred by *Carcinus maenas* 40–55 mm CW (upper panels) and 55–70 mm CW (lower panels). For comparative purposes prey size is expressed as relative prey size (RPS) = shell width/chelal height.

Elner and Hughes (1978) suggested that the feeding strategy exhibited by *C. maenas* maximized net energy intake; whereas, Sanchez–Salazar *et al.* (1987b) suggested that preference for smaller size classes of cockles probably reflected shorter absolute breaking times.

Profitability values in the present study, however, showed considerable variation, particularly from the preferred to the largest size ranges of prey consumed (Fig. 3). Examination of the data showed that small differences in shell length could result in large variations in handling time, suggesting that differences in the thickness and fracture resistance between individual prey items of similar linear length probably accounted for much of the observed variation in handling time and profitability. Moreover, the patterns of variation seem to be the result of behavioral strategies that crabs present when feeding on prey that vary little in size, yet vary markedly in vulnerability. When crabs opened smaller prey within the size range offered, breaking time was approximately constant, indicating that crushing techniques used by crabs were equally effective on all small size classes of these bivalves. This resulted in short handling time but low profitability values, although eating time, and hence handling time, constantly increased with prey size as a result of small increments in flesh weight. When crabs attempted to open a prey item of an intermediate size, the shell would sometimes yield in a short period of time, making that particular prey item highly profitable because of its relatively larger biomass. However, when the shell did not yield in the first few crushing attempts, crabs took a considerably longer time to access the flesh, resulting in reduced profitability. Microfractures in the shell substructure and possible leakage of body fluids as the shell started to break probably constituted a reinforcing cue for crabs, causing them to persist with that prey item, thereby increasing substantially handling time. Thus, prey of an intermediate but similar shell length had extremely variable profitability, although among these prey, profitability achieved its maximum value.

Because flesh weight increases approximately as the cube of shell length (Table 1); whereas, handling time increases exponentially with respect to shell length (Table 4), the time taken by crabs to handle prey successfully ultimately increased more rapidly than the biomass obtained. The lowest profitability values, therefore, generally corresponded to prey items of a larger shell length, which, although offering the greatest biomass, could only be opened by crabs using more complex and time-consuming handling techniques.

Variations in breaking time of a narrow size range of prey could be attributable to differences in hunger levels (Hughes and Elner 1979), or to learning mechanisms developed by crabs in order to manipulate prey of a particular shape (Cunningham and Hughes 1984). Age-specific differences in shell strength and morphology of individual prey items can also influence size-related preferences (Boulding 1984). Our results indicate that the lack of precision in predicting prey value could be attributable to one or more of these factors rather than to experimental designs that fail to measure handling time accurately. Furthermore, our results suggest that size selection may be the result of a mechanical process in which all encountered prey items are attacked but rejected if they remain unbroken after a certain number of opening attempts. If this latter view is correct, the decreasing order of crab preference for different size classes of prey should reflect the decreasing order of their vulnerability to crab attack. A pattern of size selection that decreases monotonically with increase in prey size corresponds to the behavioral strategy described above, and has been reported for several brachyuran crabs feeding on a variety of hard-shelled molluscan prey (e.g., Pearson *et al.* 1981, Davidson 1986, Juanes and Hartwick 1990). Moreover, authors have suggested that selection of small size classes of hard-shelled prey can minimize handling time (Hughes and Seed 1981, Seed 1990) as well as the risk of claw damage (Juanes and Hartwick 1990), thereby increasing survival of foraging crabs that may themselves be vulnerable to predation.

In the present study, however, large *C. maenas* selected intermediate size classes of *M. edulis* (Fig. 2). Earlier studies have reported that larger prey items may be less preferred, because of their robustness to crab attack; whereas, the smaller size classes of prey are less preferred simply because they are encountered less frequently, misidentified among shell debris, or frequently dropped (e.g., Elner and Hughes 1978, Rheinallt and Hughes 1985). This latter would be most likely for crabs with large, less dextrous chelae that do not allow for the efficient manipulation of small prey items. Although our study did not include experiments that presented crabs with altered proportions of different size classes of prey, observations during handling time experiments showed that large crabs often had difficulty encountering, identifying, and grasping small prey items.

Variability in handling time and profitability was even more pronounced among *C. maenas* feeding on oysters, and the size ranges of *Ostrea edulis* and *Crassostrea gigas* at which profitability attained its highest values were not clearly delimited (Fig. 3). The precise orientation of the shell within the chelae when force is first applied further influenced oyster handling time, presumably as a result of their irregular shape and resistance at different points of the shell. Furthermore, large variations in oyster profitability probably explain the lack of size-related preferences by crabs when feeding on these particular bivalves. If crabs attempted to open oysters as they encountered them, rejecting those that did not yield to the first few crushing attempts, then the oysters consumed would be those that took the least amount of time to open. Such a feeding strategy would eventually result in the more uniform patterns of size selection we observed for both *O. edulis* and *C. gigas*. Our results, therefore, emphasize the mechanistic nature of size-selective feeding in *C. maenas*. Because the diets of crabs feeding on all four prey species corresponded approximately to those predicted by optimal foraging theory, a behavioral strategy by which crabs attack all encountered prey but reject those that remain unbroken after a certain number of crushing attempts probably maximizes feeding efficiency.

Despite the variability in handling time, profitability curves varied among the species of bivalve prey used; the patterns of size selection similarly varied from one prey species to another. These results strongly suggest that differences in size-selective predation among these bivalve prey are related to the contrasting morphological features of their shells and the way these features influence the vulnerability of such prey to predation by shore crabs. Not only do these four bivalves have contrasting shell shapes, but, as they increase in size, their flesh content increases at different relative rates (Table 1). Differences in the total biomass consumed by crabs when offered each of these four prey species individually partly reflects the variations in their flesh content (Table 3). However, differences in the total number of prey items consumed suggest that consumption rates among prey species also reflect crab feeding preferences.

Sanchez-Salazar *et al.* (1987b) attributed differences in the size selection of *M. edulis* and *C. edule* by *C. maenas* to variations in

shell morphology and strength per unit length. These authors showed that the shell dimensions of cockles that could be opened by crabs of a given chelal strength were less, but the energy obtained was greater than when feeding on mussels. Accordingly, they suggested that crabs could obtain better yields by consuming cockles than mussels of a similar linear size. In the present study, profitability values for *C. maenas* feeding on cockles were over-all higher than when feeding on mussels (Fig. 3). However, the size classes of both prey species that were selected by crabs yielded similar biomass per unit time (Table 5, Fig. 4). Crabs of both size categories preferred cockles of a shell length that was slightly smaller than for the preferred mussels, but the preferred size ranges of both species were of similar shell width (Table 2). In addition, the percentage of prey consumed by all crabs decreased more steeply for cockles than for mussels among the larger size classes of prey (Fig. 2), suggesting that the ability of crabs to crush prey decreased more abruptly for cockles than for mussels as these increased in size. As the more globular-shaped cockles increase in length, shell width increases more rapidly than in the more elongate mussels; consequently, cockles have a significantly wider shell than mussels of similar shell length (Fig. 1). Because dome-shaped shells are intrinsically stronger than flatter shells (Wainwright 1969), the presence of a higher dome in the more convex cockle shell probably increased force applications required by crabs to open this infaunal bivalve. Such shell features as large size, increased thickness, greater inflation, and the absence of gape reduced the vulnerability of clams to predation by *Cancer productus* (Boulding 1984), and have been shown to influence size-related preferences of crabs (Blundon and Kennedy 1982, Seed 1993, Walne and Dean 1972) and other decapods (Griffiths and Seiderer 1980) feeding on bivalve prey.

The importance of shell shape and volume also became evident in our experiments with *O. edulis*. As prey increased in length, *O. edulis* shells became significantly higher, but much narrower than *M. edulis, C. edule,* and *C. gigas* (Fig. 1). The total shell height of *O. edulis* constituted a shape-related restriction that made crabs unable to accommodate the shell within the widest aperture of the chelae, while its smaller width prevented crabs from firmly grasping the shell in a horizontal position and applying an effective crushing force. The shape-related restriction imposed by the shell dimensions of *O. edulis* resulted in similarly long handling times over all the size ranges of oysters offered, thus explaining the lack of size selection by *C. maenas* (Fig. 2).

The patterns of oyster size-selection in our experiments accord with those previously reported for *C. maenas* when feeding on *C. gigas* and *Tiostrea (= Ostrea) lutaria* (Richardson *et al.* 1993); the latter, as with *O. edulis,* has a very flat shell. Similarly, *C. maenas* has been reported to open *C. gigas* of up to 50–60 mm SL (Dare *et al.* 1983). Although Richardson *et al.* (1993) suggested that the reluctance of *C. maenas* to feed on *T. lutaria* was perhaps related to characteristics in the shape of its shell, Dare *et al.* (1983) explained their own results in terms of the presence of thin "window" areas in the valves of *C. gigas,* which made these oysters particularly vulnerable. Our results, therefore, emphasize the importance of shell shape in determining the vulnerability of different prey species and suggest that crab preference for a particular size range of prey is more strongly related to the minimum, than to the maximum, linear dimension of the shell. As bivalves grow, their increased minimum shell dimension makes them too large to be accommodated completely within the chela, decreasing the amount of force that can be applied (Boulding 1984). Moreover, results expressed in terms of relative prey size showed that the size of prey preferred by *C. maenas* were all within the range of 0.15–0.75. The initial position of the prey within the chela during the first application of force was always with the widest, most voluminous part of the shell in the region where the dactylus and propus close to form a distinct gape. If crabs selected prey that yielded in the shortest time relative to their crushing efforts, then it is likely that they would consistently select those prey with a shell width that is equivalent to, or smaller than, the maximum height of their major chela. This is not surprising, because size-selective feeding is strongly related to chelal height (Seed and Hughes 1997) and relative prey size reflects the importance of the shape, volume, and position of prey when handled by crabs in diverse attack strategies. Thus, when crab foraging behavior is being examined, prey size based solely on shell length is not an appropriate indicator of the shell characteristics associated with crab preference; the geometry and crushing resistance of prey shells should also be taken into account.

Interspecific differences in shell shape and thickness between *Littorina rudis* and *L. nigrolineata* determined prey vulnerability to predation by *C. maenas* (Elner and Raffaelli 1980), and are, therefore, expected to influence crab preference among other prey species. Whether *C. maenas* exhibits a species-selective feeding behavior regarding these bivalve prey and whether this behavior involves an active choice will be addressed in a subsequent publication. However, in this study, crabs consumed the four prey species at different rates (Fig. 2), and the order in which prey species ranked according to consumption rates clearly paralleled the rank order of prey profitability (Fig. 4). Because differences in profitability between the selected size ranges of prey were attributable mainly to differences in their biomass, these results provide an indication that prey value could influence prey species-selection by *C. maenas*.

FORAGING BEHAVIOR OF *CARCINUS MAENAS* (L.): SPECIES-SELECTIVE PREDATION AMONG FOUR BIVALVE PREY

M. MASCARÓ* AND R. SEED

ABSTRACT Species-selective predation by medium (40–50 mm carapace width) and large (55–70 mm) *Carcinus maenas* was investigated by presenting individual crabs with paired combinations of mussels *Mytilus edulis*, flat oysters *Ostrea edulis*, Pacific oysters *Crassostrea gigas*, and cockles *Cerastoderma edule* in various proportions. When offered mussels and either oyster species simultaneously, both size categories of crabs consistently selected mussels, and food choice was independent of prey relative abundance. By contrast, *C. maenas* selected mussels and cockles as expected by the frequency in which each size category of crab encountered the preferred size ranges of prey. Crab preference clearly paralleled the rank order of prey profitability, which, in turn, was mainly determined by prey biomass, suggesting that active selection takes place at some point of the predation cycle. Decisions by crabs on whether to attack oysters and mussels initially were not influenced by the flavor or odor of their flesh. Both mussel and oyster filtrates had a similar reinforcing effect on crab perseverance to open prey. However, species-related preferences exhibited by crabs feeding at or near the optimal size suggest that foraging decisions are partly based on evaluations of over-all prey shape and volume, and that the minimum dimension of the shell constitutes an important feature that crabs recognize and associate with prey value.

KEY WORDS: Foraging behavior, *Carcinus maenas*, species-selection, bivalve

INTRODUCTION

Patterns of prey selection are the result of a sequence of specific behavioral components that a predator performs during a predation event, including the location, attack, capture or attack success, and ingestion, of prey (Hughes 1980). Feeding preferences can be partially attributable to passive or mechanistic consequences of physical properties in a predator–prey system that determine encounter rate and prey vulnerability (Rodrigues *et al.* 1987; Sponangle and Lawton 1990). However, decisions by predators on whether to attack an encountered prey item or to continue searching, or to reject or accept a prey item that is being manipulated, are still the result of an active choice (Barbeau and Scheibling 1994; Sih and Moore, 1990). To comply with Optimal Foraging Theory, these decisions must be based in part on the ability to recognize prey characteristics that correlate with profitability, defined as the potential energy yield per unit of handling time. Mechanisms of prey recognition are relatively well understood among visual hunters such as fish (e.g., Ibrahim and Huntingford 1989). Crabs, on the other hand, have been the subject of comparatively few works relating these mechanisms to optimal foraging behavior (e.g., Kaiser *et al.* 1993).

Although size-selective predation in the common shore-crab, *Carcinus maenas* (L), has been extensively documented (e.g., Elner and Hughes 1978, Elner and Raffaelli 1980, Jubb *et al.* 1983), little information is available for selective predation amongst different species of prey. This paper examines the prey species-related preferences exhibited by *C. maenas* when feeding on a variety of combinations and proportions of the mussel, *Mytilus edulis* L., the flat oyster, *Ostrea edulis* L., the Pacific oyster, *Crassostrea gigas* (Thunberg), and the cockle, *Cerastoderma edule* (L). A series of experiments testing the importance of shell shape and flesh odor/flavor in prey species selection was designed to investigate which of these characteristics determined crab decisions throughout a foraging bout.

MATERIALS AND METHODS

Species-selection experiments were performed by presenting medium (40–55 mm carapace width: CW) and large (55–70 mm CW) *C. maenas* with paired combinations of a wide size range of prey species (Table 1). Five prey items in each 5 mm-size class were scattered randomly over the floor of the aquaria and monitored twice a day. Any item consumed within each 12-h feeding period was recorded and replaced by another of similar size to maintain constant prey availability. Experiments were run continuously until a consistent feeding pattern emerged (≈10 d). Crabs and prey were collected and maintained as described in Mascaró and Seed (2000).

To establish whether crab preferences resulted from a passive response to the rate in which the prey species were presented, medium and large crabs were individually offered equal and unequal numbers of the preferred size ranges of prey in the combinations *M. edulis–O. edulis* and *M. edulis–C. edule*. The size classes of preferred prey were established on the basis of those most frequently consumed in single prey species experiments (Mascaró and Seed, 2000; Table 1) The proportions of presented prey were altered prey so that the prey species that had been preferentially selected in the previous experiments was now at the lower relative abundance of 1:2 and 1:4 with respect to the less preferred species. Each time a prey item was consumed by a crab it was immediately replaced by another of similar size, and the precise order in which prey items were taken was recorded. Once a prey item was encountered and recognized as potential food, a crab could either reject (i.e., touch, manipulate and finally abandon) or accept (i.e., successfully open and consume) the prey. Because satiation, among other factors, can strongly influence the behavioral sequence adopted by an individual crab, each trial was run for 1 h, the average period of time taken for crabs to become

TABLE 1.

Size ranges (mm in maximum shell dimension) of *Mytilus edulis* (*M*), *Ostrea edulis* (*O*), *Crassostrea gigas* (*C*), and *Cerastoderma edule* (*E*), that were offered to two size categories (mm of carapace width, CW) of *Carcinus maenas* in experiments with a wide size range of prey, and with equal and altered proportions of prey species.

Experiment	CW	*M–O*	*M–C*	*O–C*	*M–E*
Wide size	40–55	5–30	10–40	10–40	10–40
range of prey	55–70	5–30	10–40	10–40	10–40
		M	*O*	*C*	*E*
Equal and altered	40–55	10–15	10–15	10–15	5–10
proportions	55–70	15–20	15–20	15–20	10–15

Size classes were established on the basis of those most frequently selected by crabs in experiments where prey were presented individually (Mascaró & Seed 1999).

satiated during preliminary observations. Experiments were repeated on a daily basis until a consistent pattern emerged (≈5 d). The total number of times that crabs encountered each prey species were then tested for goodness-of-fit to the expected values (assuming a probability of encounter: 1:1, 1:2, and 1:4). Differences in the total number of prey of each species that were successfully opened by each individual crab were tested using the same procedure.

Two experiments were designed to examine whether preference for a certain prey species was influenced by the odor/flavor of the flesh. First, five individually maintained *C. maenas* (50–60 mm CW) were presented with 10 agar cylinders (9 × 10 mm), 5 mussel-flavored and 5 oyster-flavored. Gels were made using a filtrate of 10 g of either mussel or oyster flesh homogenized in 100 mL of seawater; this was then mixed with 20 g of agar and poured to a depth of 10 mm into petri dishes. When set, the cylinders were cut using a 9-mm diameter cork borer and stored at −10 °C. The number of cylinders that were attacked was monitored every 10 min during a period of 1 h. Differences among the number of each type of cylinders destroyed within 10, 30 and 60 min were tested for goodness-of-fit to equal expected numbers.

The second experiment presented individually maintained *C. maenas* of 50–60 mm CW with models made of mussel and oyster shells 15–20 mm in shell length (maximum linear dimension of the shell) filled with either mussel or oyster gel. Intact bivalves were briefly immersed in boiling water to remove all the flesh and thoroughly clean the shells. Empty shells were then dried, and a hole was drilled through the valves so that these could be closed together with fuse wire. Rectangular pieces of gel cut using scalpel were carefully held between the valves, which were then pressed and tied together. Five individually maintained crabs were offered 5 mussel shells + mussel gel and 5 mussel shells + oyster gel; a further five crabs were offered 5 oyster shells + mussel gel and 5 oyster shells + oyster gel. Each time a crab opened a model, the model was replaced by another of the same type to maintain constant availability. The time that elapsed from the moment a crab grasped a model, until that model, whether it was intact or not, was finally abandoned was recorded with a stopwatch, and defined as persistence time. The number of models that were accepted and rejected within 1 h was recorded. The total number of times that each crab encountered each model type (i.e., models with similar shells but different gel) was then tested for goodness-of-fit to the expected values (assuming an equal probability of encounter). Differences in the total number of models that were accepted by each individual crab were tested using the same procedure. Comparisons of persistence time between models of similar shell types but different gel contents were examined using 2-sample *t*-tests on previously log-transformed data.

To assess the importance of shell shape on crab feeding preferences, experiments were carried out by presenting medium and large *C. maenas* with inedible models of comparable size and weight to those of the preferred live prey (Table 1). Models of zero profitability were constructed by filling empty shells of the preferred size range of each prey species with epoxy resin. Models were left 24 h in sea water to eliminate the smell of resin. The combinations of models offered were the same as for the live prey experiments. Trials consisted of presenting four *C. maenas* (50–60 mm CW), each maintained separately, with a sequence of six models of the same prey species. As soon as a crab finished manipulating one model in the sequence, it was presented with the next. On day 1, two crabs were presented with six models of a certain species, and two crabs were presented with six models of another. On day 2, the treatment was reversed so that each crab was presented with a paired combination of model prey (*M–O*, *M–C*, *O–C*, and *M–E*) Persistence time with each model was recorded with a stopwatch and data were logarithmically transformed before analysis of variance using a balanced design with "model in sequence" and "model type" as fixed factors, and "crab" as a random factor.

The importance of shell shape in determining crab persistence was further examined by presenting *C. maenas* of 50–60 mm CW with epoxy resin models of three contrasting geometric shapes: a "cockle" (sphere: 904 mm^3), a "mussel" (wedged rectangle: 420 mm^3), and an "oyster" (flat disc: 530 mm^3; Fig. 1). The resin models were similar in length (maximum linear dimension, all: 12–15 mm) but differed in their height (maximum linear dimension of the axis at right angles to their length: sphere: 12 mm;

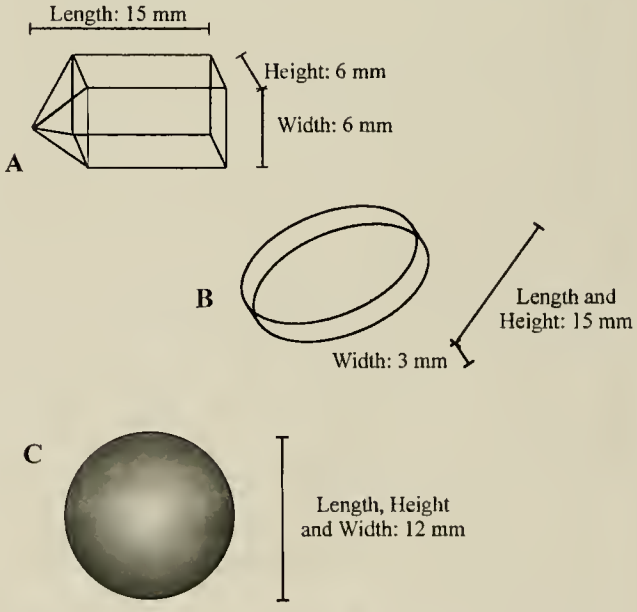

Figure 1. Epoxy resin models of contrasting geometric shapes that were offered to *Carcinus maenas* (50–60 mm CW) to examine the importance of shell shape in crab forging behavior: A) wedged rectangle (420 mm^3), B) flat disc (530 mm^3); C) sphere (904 mm^3).

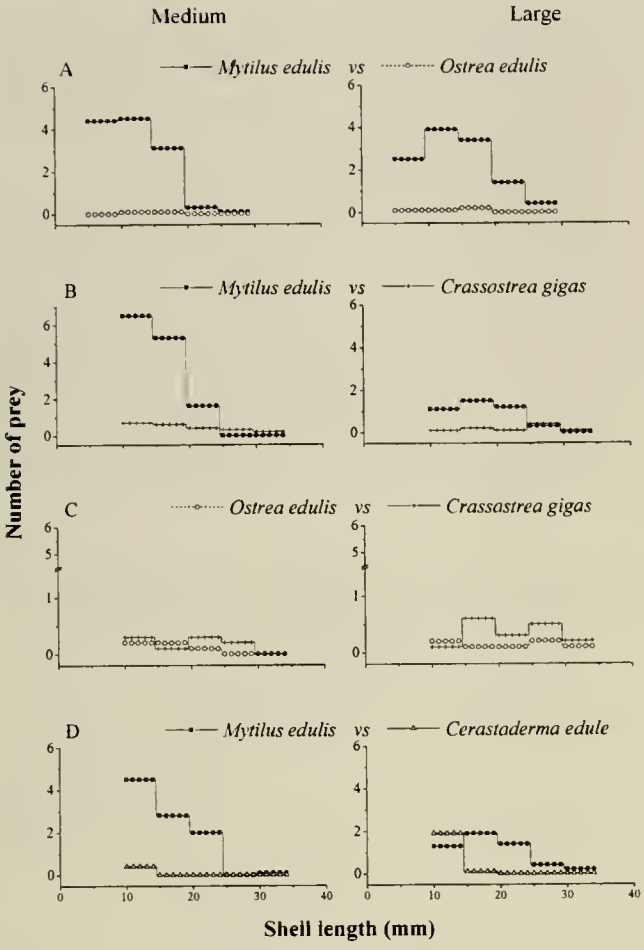

Figure 2. Number of prey of various size classes that were consumed by medium (40–55 mm CW) and large (55–70 mm CW) *Carcinus maenas* during experiments where crabs were offered prey species in paired combinations: (A) *M. edulis–O. edulis*, (B) *M. edulis–C. gigas*, (C) *O. edulis–C. gigas*, (D) *M. edulis–C. edule*. Values are mean consumption rates • $crab^{-1}$ day^{-1}. Note change in scale in (C).

rectangle: 6 mm; disc: 15 mm) and width (minimum linear dimension: sphere: 12 mm; rectangle: 6 mm; disc: 3 mm). On each day, six individually maintained crabs received a sequence of five models of one of the three model types and their persistence times with these models were recorded. Over a 3- d period, each crab had experienced each of the different model types. After each trial, crabs were fed on mussel flesh for 1 h before being starved until the following day. The order in which each crab experienced the different model types was random. Data were logarithmically transformed before differences in persistence time were examined by analysis of variance (ANOVA) using a balanced design with "model in sequence" and "model type" as fixed factors and "crab" as a random factor.

RESULTS

When *M. edulis* was offered in combination with either *O. edulis* or *C. gigas*, both medium (40–55 mm CW) and large (55–70 mm CW) *C. maenas* showed a strong preference for mussels (Fig. 2a,b). When offered a choice between *O. edulis* and *C. gigas*, neither size group of crabs showed any preference for either oyster species (Fig. 2c). When given a choice between *M. edulis* and *C. edule*, medium-sized *C. maenas* clearly preferred mussels; whereas, large crabs consumed similar numbers of both prey of 10–15 mm long, but only consumed mussels from the larger size classes (Fig. 2d).

When crabs were presented with both equal and unequal numbers of the preferred size ranges of *M. edulis–O. edulis*, the percentage of mussels opened by medium and large *C. maenas* (77%–100%) was always significantly higher than that of oysters (Table 2). By contrast, the proportion of *O. edulis* accepted by crabs was never greater than 23%, even when the alternative species was scarce. Of all the mussels encountered, very few were rejected; whereas, any encountered *O. edulis* were only occasionally consumed, and were frequently rejected before the crabs had attempted to open them. Although the percentage of rejected oysters was always high, the already low percentage of rejected mussels in the 1:2 ratio experiments decreased even further in the 1:4 ratio experiments, where mussels were at their lowest relative abundance (Table 2). Results of goodness-of fit tests showed that the number of observed encounters was not significantly different from those expected in all mussel-oyster combination trials (χ^2 from 0.22–2.84, all at $P > 0.05$), suggesting that consumption rates were not influenced by prey encounter rates.

In experiments with equal and unequal numbers of the preferred size ranges of *M. edulis–C. edule*, however, the percentage of accepted and rejected prey varied according to the rates in which prey species were encountered (Table 2). Of the total number of prey accepted by large crabs, the percentage of *M. edulis* decreased when mussels were less abundant. Similarly, the percentage of accepted *C. edule* increased as their relative abundance

TABLE 2.

Percentage and numbers (in parenthesis) of *Mytilus edulis*, *Ostrea edulis*, and *Cerastaderma edule* that were accepted or rejected by *Carcinus maenas* 40–55 and 55–70 mm CW in experiments where crabs were presented with the preferred size classes of mussels and oysters and mussels and cockles in proportions of 1:1, 1:2, and 1:4.

	rej	11 (0.6)	89 (4.8)	56 (1)	44 (0.8)

Values are mean consumption rates per crab over 1-h periods during 4–5 consecutive days: * denotes prey species accepted in significantly higher numbers than expected ($P < 0.01$); NTA = cases in which results did not allow for chi-square tests to be applied; ns = no significant differences; acc = accepted; rej = rejected.

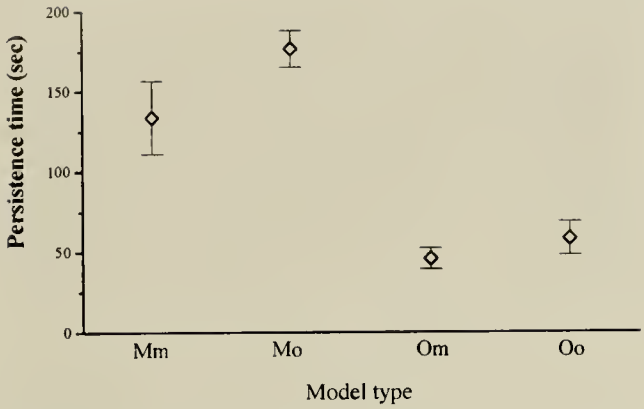

Figure 3. Mean persistence time (sec ± se) taken by *Carcinus maenas* (50–60 mm CW) to open shells of either *Mytilus edulis* (M) or *Ostrea edulis* (O) filled with gels made from either mussel (m) or oyster (o) filtrate.

increased. Large crabs encountered both prey species as expected by the proportions in which they were presented (χ^2 from 0.03–1.63, all at $P > 0.05$). Although medium-sized crabs also accepted mussels and cockles in the same proportions as they encountered them, the encounter rates of mussels and cockles did not correspond to the relative abundance in which prey were offered (1:1 trial: $\chi^2 = 7.48$, $P < 0.05$; 1:2 trial: $\chi^2 = 9.6$, $P < 0.01$ and 1:4 trial: $\chi^2 = 25.77$, $P < 0.001$, respectively). Medium-sized crabs encountered mussels and cockles in statistically indistinguishable numbers in the 1:2 ratio trial ($\chi^2 = 0.05$, $P > 0.05$), and encountered mussels at approximately half the rate that they encountered cockles in the 1:4 ratio trial ($\chi^2 = 1.85$, $P > 0.05$).

When *C. maenas* (50–60 mm CW) were offered a choice between mussel and oyster agar cylinders, these were readily accepted whenever they were encountered. No significant differences in the number of mussel and oyster agar cylinders accepted after 10 min, 30 min, and 1 h were detected (χ^2 from 0.08–0.89, all at $P > 0.05$). When crabs were presented with mussel shells filled with either mussel or oyster gel, they encountered and accepted both model types in similar proportions (encountered: $\chi^2 = 0.31$; $P > 0.05$; accepted: $\chi^2 = 0.20$; $P > 0.05$). When oyster shells filled with either mussel or oyster gel were offered, the encounter rates for both model types were again similar ($\chi^2 = 2.25$; $P > 0.05$), and crabs again accepted similar numbers of oyster shells filled with either type of gel ($\chi^2 = 0.15$; $P > 0.05$). Because crabs showed no apparent preference for one type of gel over the other, results from experiments with different types of gel but similar types of shell were combined. Comparisons of results among experiments with mussel shells and those with oyster shells showed that, although crabs encountered significantly more oyster shells than mussel shells ($\chi^2 = 16.46$; $P < 0.001$), they accepted mussels and oysters in similar proportions ($\chi^2 = 1.13$; $P > 0.05$). Crabs, however, rejected a significantly higher proportion of oyster shells than mussel shells ($\chi^2 = 26.28$; $P < 0.001$), so that in experiments with oyster shells, crabs actually rejected most of the models encountered.

Crabs persisted for similar periods of time with mussel shells filled with either mussel or oyster gel (133.9 ± 21.5 and 176.5 ± 10.8 sec, respectively; $t = -1.84$; $P > 0.05$; Fig. 3). Persistence times were also similar amongst oyster shells filled with either mussel or oyster gel (45.9 ± 6.5 and 58.4 ± 10.2 sec, respectively; $t = -1.01$; $P > 0.05$). Because persistence times with different gel types were in each case similar, results for similar types of shell were combined. Persistence times for mussel shells were significantly longer than for oyster shells regardless of the type of gel with which they had been filled ($t = 7.79$, $P < 0.001$). In summary, our results indicate that prey choice is based on shell shape and strength rather than flesh odour.

When offered five epoxy resin models in sequence, *C. maenas* (50–60 mm CW) persisted for significantly shorter periods of time through the sequence of the first to the last model in all species presentations (*M–O*: $F = 6.78$; $P < 0.001$; *M–C*: $F = 47.16$; $P < 0.001$; *O–C*: $F = 13.23$; $P < 0.001$; *M–E*: $F = 6.31$; $P < 0.001$; Table 3; Fig. 4). Crabs persisted significantly longer with the first model of *M. edulis* presented than with either the *O. edulis* or *C. gigas* models in the *M–O* and *M–C* combinations ($F = 131.76$; $P < 0.001$; $F = 104.60$; $P < 0.001$, respectively), and persisted significantly longer with the first *C. gigas* than with the first *O. edulis* in the *O–C* combination ($F = 18.53$; $P < 0.001$). However,

ANOVA: Persistence time = sequence · model type (fixed factors); crab (random factor).

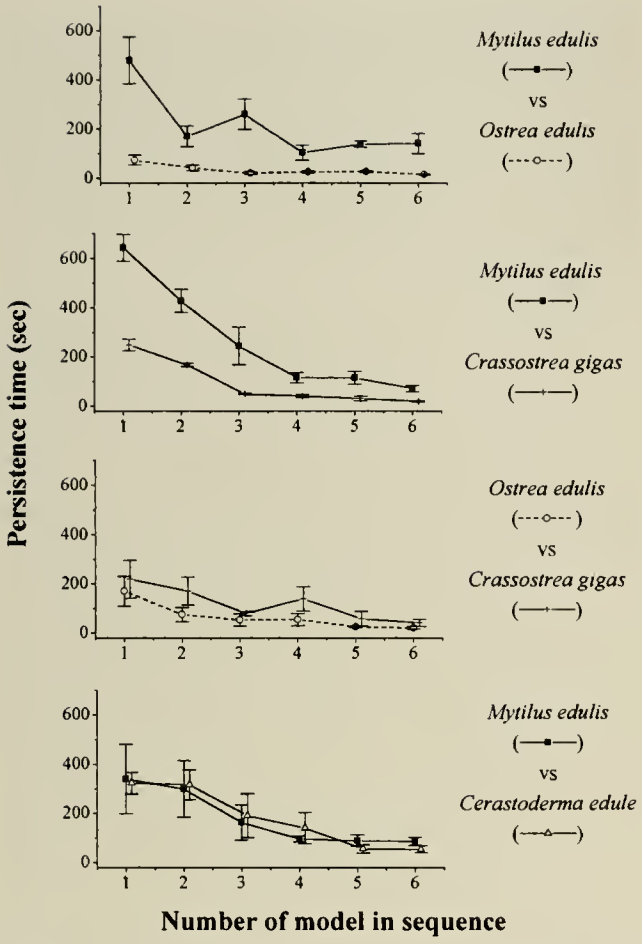

Figure 4. Mean persistence time (sec ± se) for inedible models of *Mytilus edulis*, *Ostrea edulis*, *Crassostrea gigas*, and *Cerastoderma edule* when presented sequentially to *Carcinus maenas* of 50–60 mm CW.

crabs did not differ in their persistence times with the first models of either type in the *M–E* combination ($F < 0.01$; $P > 0.05$). The lack of any significant contribution of the interaction between the model in sequence and model type to the over-all variance of the data for all prey combinations (F from 0.54–1.87; $P > 0.05$) indicates that the decrease in persistence times throughout the sequence of presentation was similar regardless of the type of prey handled by the crabs. Significant differences in the persistence time between individual crabs in the *M–C* ($F = 3.70$; $P < 0.05$), the *O–C* ($F = 19.41$; $P < 0.001$), and the *M–E* ($F = 3.07$; $P < 0.05$) combinations indicates that some of the variability in persistence time is attributable to unexplained differences among individual crabs. However, no significant differences were detected among the crabs in the *M–O* combination ($F = 1.87$; $P > 0.05$; Table 3).

When *C. maenas* (50–60 mm CW) were presented with epoxy resin models of three contrasting geometric shape, persistence time decreased significantly through the sequence of models regardless of their shape (Fig. 5; $F = 20.46$; $P < 0.001$). Although the decrease in persistence time was similar for all three geometric shapes ($F = 0.75$; $P > 0.05$), crabs persisted for a significantly longer period of time with the first sphere and wedged rectangle than with first flat disc ($F = 7.31$; $P < 0.001$). No significant differences in persistence time among individual crabs were detected ($F = 2.00$; $P > 0.05$).

Taken overall, the results of the experiments with epoxy resin models indicate that crabs initially preferred those with a larger minimum dimension (i.e., models of mussels and cockles, and models in the shape of a sphere and a wedged rectangle). Persistence time, however, decreased with increasing number of models in the sequence in a similar rate regardless of model type, suggesting that shell shape does not influence the rate at which preference declines when crabs handle food items of zero profitability.

DISCUSSION

Many studies have related crab preference to the selection of prey with a higher value or profitability, expressed as the net energy intake per unit of handling time (Elner and Hughes 1978, Elner and Raffaelli 1980). However, authors have noted that selection of optimum prey could result from a greater chance of encountering items with a larger surface area and/or reduced handling times because of a lower predatory resistance (Barbeau and Scheibling 1994), in which case, prey selection should be considered to be a consequence of passive choice. Passive or mechanistic prey selection usually results from physical properties and behavior of both predator and prey (Hughes 1980) that determine the probability of encountering and opening alternative prey types. Body size, speed of movement, and density of predator and prey can influence the probability of encountering, recognizing, and predicting valuable prey (Lawton 1989); whereas, contrasting morphologies in bivalve shells and the mechanical properties involved in crab attack can affect prey vulnerability (Boulding 1984, Brown and Haight 1992), and hence the probability of opening encountered prey (Sih and Moore, 1990).

When crabs were offered a wide size range of oysters and mussels simultaneously, both medium (40–55 mm CW) and large (55–70 mm CW) crabs consistently selected mussels (Fig. 2). Furthermore, results of experiments with *M. edulis* and *O. edulis* in equal and altered proportions suggest that preference for mussels, and the apparent lack of preference for oysters, are independent of the relative abundance in which either prey species are presented (Table 2). Previous authors have shown that *C. maenas* consumed *M. edulis* at more than twice the rate at which they consumed *C. gigas* (Dare *et al.* 1983); whereas, *Cancer novaezelandiae* also preferred mussels when offered a choice of mussels and gastropods (Creswell and McLay, 1990).

Barbeau and Scheibling (1994) indicated that active selection can be considered to be an important component of predation when a predator selects a prey type more often than expected when given a choice of prey types than when not given a choice (see also Liszka and Underwood 1990). In our study, comparisons of prey consumption rates in single and multiple choice experiments could not be made, thus, active and passive components could not be analyzed in this way. However, the preference for *M. edulis* exhibited by *C. maenas* was consistent throughout experiments where prey types were encountered in varying and contrasting proportions (Fig. 2; Table 2). In earlier single species experiments involving *M. edulis*, *O. edulis*, *C. gigas*, and *C. edule* designed to establish whether prey selection in *C. maenas* was size related, the order in which prey species were ranked according to consumption rates clearly paralleled the rank order of species profitability (Mascaró and Seed 2000). We reported that differences in profitability between prey species were mainly attributable to differences in their biomass, rather than to differences in breaking time. These results suggest that prey value can influence prey species-selection

and that crab preference for mussels in the present study involves an active component of selection at some point of the predation cycle.

When *C. maenas* were offered *M. edulis* and *C. edule* in various proportions, species selection was strongly influenced by the frequency in which each size category of crabs encountered prey (Table 2). Although active selection could not be invalidated (*sensu* Barbeau and Scheibling 1994), the close agreement in the proportions of accepted and encountered prey items suggests that the active component of selection in this particular prey combination is not important in determining crab preference. The observed differences in the foraging behavior of *C. maenas* when feeding on a combination of mussels and oysters and a combination of mussels and cockles further supports the view that the relative importance of active and passive selection in explaining prey choice may differ with each predator–prey system (Abele *et al.* 1981).

For active prey selection, mechanisms must exist by which crabs are able to recognize prey characteristics that correlate with their potential value. Among prey near the optimal size, such characteristics as shell shape or flesh odor/flavor may have an important effect on foraging decisions. Amino acids can be readily differentiated by *C. maenas* during searching (Shelton and Mackie 1971) and feeding phases (Case and Gwilliam 1961). Our results show that crabs were not attracted any more often to gel cylinders made from mussel-flesh filtrate than to those containing oyster-flesh filtrate. Crabs attacked both types of cylinders whenever these were encountered and this behavior persisted throughout the duration of the feeding trials, suggesting that preference for either type of flavor was not modified once crabs had experienced the gels.

A study of the factors affecting diet selection in *C. maenas* demonstrated that shore-crabs are sensitive to different concentrations of mussel flesh filtrate, and suggested that, despite dilution effects, crabs may be able to distinguish mussels of varying quality by responding to odor (Kaiser *et al.* 1993). In addition, these authors indicated that olfactory stimuli had a reinforcing effect on crab preference, because crabs readily picked up and manipulated both models with and without mussel filtrate, but more quickly rejected those that did not incorporate the chemical stimulus. Our experiments did not include any examination of different concentrations of flesh filtrate, but mussel and oyster flesh filtrates had a similar reinforcing effect on the perseverance with prey, and crabs initially attacked either type of model irrespective of their flavor (Fig. 3). These results provide further evidence of the reinforcing effect of olfactory and taste stimuli, and comparisons with previous reports suggest that perhaps the concentration, rather than the specific chemical composition, of flesh might be involved in prey attractiveness to crabs (Shelton and Mackie 1971). Our results do, however, suggest that certain characteristics of the shells of *M. edulis* and *O. edulis* might provide mechanical stimuli that influence decisions by crabs initially to attack and to persist with prey that is already being manipulated (Fig. 3).

When attacking hard-bodied, resistant prey, predatory crabs show relatively stereotyped patterns of behavior (Lau 1987, Seed 1993), but details of this behavior can be influenced by specific morphological characteristics among prey of different size (Elner and Hughes 1978). Over a relatively narrow range of prey size; however, shape can have a marked influence on the handling process (Boulding 1984, Griffiths and Seiderer 1980), and information gained by crabs while rotating prey with the chelae and mouth parts can be crucial in deciding whether or not the attack is continued or aborted (Akumfi and Hughes 1987). In experiments where *C. maenas* were offered a sequence of five models of each prey species, crabs persisted longer with the first model of a mussel to be offered than with the first model of an oyster, and they also persisted longer with the first model of *C. gigas* than with *O. edulis* (Table 3; Fig. 4). These results suggest that the initial reluctance of crabs to attack flat oysters and their propensity to attack mussels, are not associated with differences in the ultimate energetic reward, but could be based on an evaluation of the overall shape and/or volume of the shells of these bivalves during a first recognition phase.

Further investigation of the importance of shell shape in species selection showed that *C. maenas* persisted much longer with the first models that resembled both the shape of a cockle (sphere) and a mussel (wedged rectangle) than with the first model that resembled a flat oyster (disc; Fig. 5). The resin models used had a similar length, but differed in their height and width, the flat disc having the smallest width of the three models (Fig. 1). If crabs evaluate prey on the basis of shell width rather than length, they would be expected to persist longer on those shells having the greatest width. A strong association between shell width and volume is suggested by the significantly greater increase in shell width with increasing shell length in cockles and mussels, compared to flat oysters, and by flat oysters having significantly less flesh weight than mussels and cockles of comparable shell length (Mascaró and Seed 2000). Furthermore, *C. maenas* obtained the greatest profitability when feeding on cockles and mussels (Mascaró and Seed 2000), and *C. edule* and *M. edulis* were included in crab diets more frequently than *O. edulis* throughout the species-selection experiments (Table 2, Fig. 2). These results suggest that shell width; that is, the minimum linear shell dimension, probably constitutes an important morphological characteristic that crabs are able to evaluate and associate with potential prey value.

Previous studies have reported that the minimum shell dimension is an important characteristic determining prey size and species selection in crabs (Boulding 1984) and in other decapods (Griffiths and Seiderer 1980). In experiments where *C. maenas* was presented with Perspex models of different shape and size, Kaiser *et al.* (1993) found that changes in model length had little influence on handling time, because the mechanical efficiency of the chelae was determined by the cross-sectional profile of the prey. These authors further suggested that those models that more closely resembled the shape of a mussel (wedged rectangle) allowed the chelae to operate at maximum mechanical advantage and improved handling efficiency. Mascaró and Seed (2000) re-

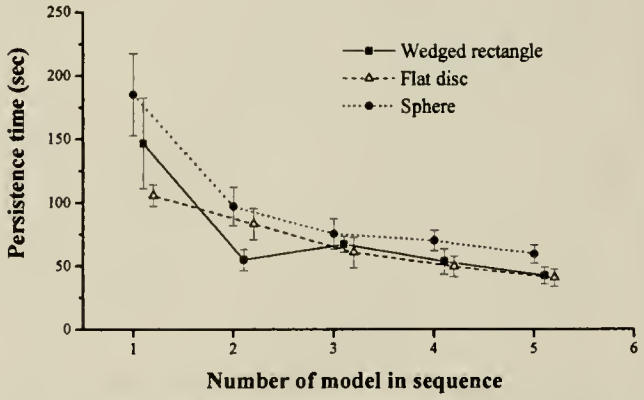

Figure 5. Mean persistence time (sec ± se) for inedible models of three contrasting geometric shapes (wedged rectangle, flat disc and sphere) that were presented sequentially to *Carcinus maenas* of 50–60 mm CW).

ported that the relative prey size (= shell width/maximum cross-sectional dimension of the major chela) preferred by *C. maenas* consistently had values <1, suggesting that the position in which the width of the shell fitted within the chela was significant in determining attack success of the preferred size classes of prey. In the present study, flat oysters were more difficult to accommodate within the chela than were mussels. Although flat oyster shells are very narrow, their large shell length and height reduce their handling efficiency. In contrast, mussel shells with only one of its linear dimensions being large, can be accommodated within the chela either with its height or its width in the gape between propus and dactylus.

If foraging decisions by crabs were based on shell width, then some patterns of species selection by *C. maenas* observed in this study could be explained. The observed similarity in consumption rates of *M. edulis* and *C. edule* might be attributable to the similarity in shell width of the (different) size classes of these prey offered (Table 1). When crabs were offered similar size classes of *M. edulis* and *O. edulis*, they preferentially consumed mussels probably because of the differences in shell width between the (similar) size classes of prey presented (Table 1).

Although some portunids can use vision to locate their prey (Hughes and Seed 1981, Seed and Hughes 1997), crabs are essentially nonvisual predators. This makes olfactory stimuli the predominant factor directing crabs toward potential prey (Barber 1961). Although different concentrations of chemical compounds elicit different components of the searching response (i.e., locomotory or probing and grasping reflexes; Zimmer-Faust and Case 1982), our results suggest that during this initial phase, differences in flesh odor/flavor between different prey species did not seem to influence prey selection. Once crabs have physically encountered a prey item, shape and size of the shell assume a greater significance than flesh odor, interacting with chemical and mechanical stimuli from alternative prey touched by the pereiopods (Jubb *et al.* 1983). Our results emphasize the importance of certain shell characteristics and suggest that those dimensions more strongly associated with prey volume (e.g., shell width), and, hence, the amount of potential flesh, might be predominant in deciding whether a crab attacks. Once a food item has been recognized and an attack initiated, further decisions can be influenced by several factors, including microfractures within the shell structure (Boulding and LaBarbera 1986) and leakage of body fluids that stimulate crabs to persist with the attack. Stimuli from alternative prey may also deter crabs in their opening attempts. Moreover, it is at this stage, when a prey item that does not yield easily to the crab's crushing efforts can be abandoned. Thus, prey vulnerability, together with the tenacity and experience of crabs might be particularly relevant at this point of the encounter. Although our results do not allow a hierarchical order of crab responsiveness to various prey stimuli to be defined, they do emphasize that odor and shape assume different importance at several decisive moments of the foraging bout, and that by using a variety of stimuli to assess prey quality, crabs probably enhance their predatory efficiency.

ACKNOWLEDGMENTS

We are grateful to Mr. Peter Millican, The Centre for Environment, Fisheries, and Aquaculture Science, Conwy, North Wales for supplying the oysters used in these experiments. We thank Dr. C. Whittaker and Dr. J. Martins for their advice concerning statistical analysis. ABSTRACT Estuarine organisms routinely encounter fluctuations in dissolved oxygen, carbon dioxide, and pH, which can vary both seasonally and diurnally. Such environmental stresses as hypoxia can affect the immune response of invertebrates and vertebrates and have been linked to increased disease incidence. This research investigated the effects of hypoxia, hypercapnia, and low pH on disease susceptibility in both penaeid and palaemonid shrimp. Juvenile penaeid shrimp *Litopenaeus vannamei* and adult grass shrimp *Palaemonetes pugio* were challenged by intramuscular injection with a previously determined LD_{50} dose of a known pathogenic strain of *Vibrio parahaemolyticus*. Mortalities were monitored for shrimp held under normoxia (Po_2 = 150–155 torr, Pco_2 = 0.23 torr, pH = 7.6–8.0 for *L. vannamei*, Po_2 = 150–155 torr, Pco_2 = 0.23 torr, pH = 8.0–8.2 for *P. pugio*) and two levels of hypoxia. The penaeid shrimp were challenged under normocapnic hypoxia (Po_2 = 45 torr, Pco_2 = 0.23 torr, pH = 7.8–8.1) and hypercapnic hypoxia (Po_2 = 30 torr, Pco_2 = 15.2 torr, pH = 6.8–7.0). Grass shrimp were challenged under two levels of hypercapnic hypoxia (Po_2 = 45 torr and 30 torr, Pco_2 = 15.2 torr, pH = 6.7–7.0). Both the juvenile *L. vannamei* and the adult *P. pugio* held under hypercapnic hypoxia at 30 torr oxygen displayed significantly lower 48-hour survival (15.7 and 3.1%, respectively) than animals held in normoxic water (28.7 and 29.4%, respectively). There was no significant decrease in survival in *L. vannamei* under normocapnic hypoxia at 45 torr oxygen or in *P. pugio* under hypercapnic hypoxia at 45 torr oxygen. Total hemocyte count (THC/mL) significantly decreased in adult *L. vannamei* held under hypercapnic hypoxia when compared to normoxic controls. Oxygen level had a significant effect on total hemocyte density; whereas, time and the interaction of time and oxygen did not. The reduction in THC/mL may contribute to an increased rate of mortality in shrimp held under hypoxic conditions and challenged with *V. parahaemolyticus*. These results show that hypercapnic hypoxia decreases survival following bacterial challenge in both *L. vannamei* and *P. pugio* and decreases total hemocyte count in *L. vannamei*. These data provide direct evidence that naturally occurring variations in oxygen, CO_2 and pH can place estuarine organisms at increased risk from opportunistic pathogens

INTRODUCTION

Penaeid and Palaemonid shrimp in estuarine waters frequently encounter levels of dissolved oxygen, carbon dioxide, and pH that vary dramatically on a diurnal and seasonal basis. Shallow coastal regions in the southeast and in the Gulf of Mexico often experience dissolved oxygen concentrations less than 3.0 mg/L (Breitburg 1990, Rabalais et al. 1994, Burnett 1997, Summers et al. 1997). In South Carolina tidal marshes, tidal creek oxygen pressures can fluctuate between 9 and 170 torr (6% and 110% air saturation) within a 24-hour period (Cochran and Burnett 1996). Oxygen levels as low as 1.2% air saturation (approximately 2 torr) have been measured in the nearby Savannah River estuary (Winn and Knott 1992). Moreover, hypoxia is almost always accompanied by an increase in carbon dioxide pressure (Pco_2), or hypercapnia, produced by respiration. Elevated levels of water CO_2 then drive a decrease in water pH. Cochran and Burnett (1996) reported that Pco_2 varies from 0.3 to 12 torr, and pH ranges from 6.5 to 7.6 in South Carolina tidal marshes. Thus, hypoxia and low pH often co-occur in the natural environment (Burnett 1997).

Shrimp raised in aquaculture ponds also experience severe changes in O_2, CO_2, and pH because of high density and nutrient input from feed (Browdy et al. in press, Madenjian 1990). Dissolved oxygen levels are routinely measured in well-managed farm ponds, with the general understanding that low O_2 levels may be lethal to shrimp. Supplemental aeration is used to reduce fluctuations in dissolved oxygen; however, periods of hypoxia and hypercapnia still occur in routine management (Chang and Ouyang 1988, Garcia and Brune 1991).

Although extreme hypoxia or anoxia can cause mass mortalities in estuarine organisms (Garlo et al. 1979, Winn and Knott 1992, Diaz and Rosenberg 1995, Lenihan and Peterson 1998), sublethal hypoxia may have an adverse impact on normal physiological functions in shrimp, such as osmoregulatory capacity (Charmantier et al. 1994) and molting (Clark 1986). Hypoxia also can suppress immune function in shrimp. Direkbusarakom and Danayadol (1998) found that hypoxia (1.8–2 ppm) decreased phagocytosis and bacterial clearance efficiency in the black tiger shrimp, *P. monodon*. In addition, Le Moullac et al. (1999) reported a decrease in hemocyte numbers and respiratory burst activity of *Litopenaeus stylirostris* exposed to severe hypoxia (1 mg O_2/L). These observations suggest that chronic sublethal hypoxia might suppress the ability of shrimp to resist infections with opportunis-

*Corresponding address: Louis E. Burnett, Grice Marine Laboratory, 205 Fort Johnson, Charleston, SC 29412. E-mail: burnettl@cofc.edu

tic pathogens such as environmental bacteria, viruses, and fungi. Indeed, Le Moullac (1999) demonstrated that the levels of hypoxia that decreased hemocyte numbers and suppressed respiratory burst activity in *L. stylirostris* also increased pathogenicity of *Vibrio alginolyticus* in that shrimp species.

Unfortunately, most studies of hypoxia ignore changes in CO_2 and pH associated with hypercapnic hypoxia (Burnett 1997). Where the effects have been assessed, low pH and high CO_2 enhanced mortality rates of extreme hypoxia (Martinez et al. 1998) and altered metabolic activity (McCulloch 1990). Low pH independently and additively with hypoxia suppressed the respiratory burst of oyster hemocytes (Boyd and Burnett 1999). The latter study strongly suggested that hypercapnic hypoxia suppresses the resistance of wild and aquacultured estuarine organisms against such naturally occurring opportunistic pathogens as bacteria, viruses, and fungi.

In the last 10 years, several highly lethal bacterial pathogens have had a serious impact on both wild and aquacultured populations of penaeid shrimp (Karunasagar et al. 1994, Mohney et al. 1994, Hiney 1995, Liu et al. 1996, Alapide-Tendencia and Dureza 1997, Lavilla-Pitogo et al. 1998). The most frequently reported bacterial infection in penaeid shrimp is vibriosis, caused by bacteria from the family Vibrionaceae (Adams 1991, Sahul Hameed 1995). Bacteria in the family Vibrionaceae comprise 10–50% of the marine heterotrophic bacteria found in coastal waters (Thune et al. 1993). Among several *Vibrio* species associated with this disease, *Vibrio parahaemolyticus* is frequently associated with disease outbreaks in aquaculture (Mohney et al. 1994, Sahul Hameed 1995) and is sometimes found at high densities in coastal waters (Buck 1990, DePaola et al. 1990).

In this study, we evaluated the impact of hypoxia and hypercapnic hypoxia on resistance to the opportunistic bacterial pathogen *V. parahaemolyticus* in two commercially and recreationally important species of shrimp. The Pacific white shrimp, *Litopenaeus vannamei,* is the species of choice for penaeid shrimp aquaculture in South Carolina. *L. vannamei* occurs naturally from the Gulf of California to northern Peru (Perez Farfante and Kensley 1997), but is imported for use in aquaculture because of its faster growth over native species (Sandifer et al. 1993). The grass shrimp, *Palaemonetes pugio,* serves an important role in the estuary as a detritivore by consuming and breaking down *Spartina* and aiding in trophic level energy transfer (Welsh 1975). They also serve as prey for many important commercial and recreational fishes and crustaceans, which use the marsh as nursery grounds (Welsh 1975). In the first phase of these experiments, an intramuscular bacterial challenge model with survival endpoint was developed and applied in both shrimp species to determine LD_{50} values for *V. parahaemolyticus.* Then, to evaluate the contribution of hypoxia and hypercapnic hypoxia to disease resistance, survival was monitored in shrimp challenged with LD_{50} doses of *V. parahaemolyticus* and exposed to varying levels of water O_2, CO_2, and pH. Finally, to determine whether hypercapnic hypoxia might alter cellular components of the shrimp immune system over the time course of these bacterial challenges, total hemocyte densities of the hemolymph (THC/mL) were compared in animals exposed to normoxia and hypercapnic hypoxia.

MATERIALS AND METHODS

Experimental Animals

Litopenaeus vannamei (Boone) from specific pathogen-free stocks were provided by the Waddell Mariculture Center in Bluffton, South Carolina, by Island Fresh Seafood in Yonges Island, South Carolina, and by Dixieland Maricultural Farms in Hollywood, South Carolina. Shrimp were maintained in well-aerated recirculating seawater at 28–32 ppt salinity, 23–25 °C, and pH 8.0–8.2. Water quality variables (pH, salinity, and temperature) were measured every other day. Ammonia was monitored twice a month and remained lower than 0.25 mg/L. Animals were fed once daily with shrimp feed (Zeigler Brothers, Inc). All necessary precautions were followed for possessing a nonindigenous shrimp species as outlined in the nonindigenous shrimp possession permit #NI98-0565 granted by the South Carolina Department of Natural Resources.

Grass shrimp *Palaemonetes pugio* (Holthuis) were collected with a dip net in a nearby tidal creek. These shrimp were held in a 50-gallon aquarium at 25–27 ppt salinity and 23–25 °C for at least 2 days before use in an experiment. Animals were fed Marine Tetra Flakes daily.

Bacteria

A known pathogenic strain of *Vibrio parahaemolyticus* (90-69B3) was streaked on a Tryptic Soy Agar (TSA) plate with 2.5% NaCl added and allowed to grow overnight at room temperature. Aliquots (0.5 mL) of the bacteria were stored in freezing media (Tryptic Soy Broth (TSB) + 2.5% NaCl and 20% glycerol) at −70 °C. These aliquots were used as the working stock.

For each assay, *V. parahaemolyticus* was streaked onto TSA + 2.5% NaCl plates from the frozen aliquots and allowed to grow at room temperature for 24 hours before use. A different aliquot was used for each assay to avoid excessive passages of the bacteria on plates. Bacteria were transferred from the plates to 2.5% NaCl buffered with 20 mmol/L HEPES using wooden applicator sticks. Bacterial densities were quantified by optical density (OD) at 540 nm and then serially diluted in the saline to obtain the test dosages. OD values were confirmed by counting colony-forming units on double layer plates (10 mL of marine agar containing the bacterial dilution overlaid onto 10 mL of TCBS agar). OD values of 0.1 and 1.0 were determined to be equal to 1.0×10^8 colony-forming units per mL (CFU/mL) and 1.0×10^9 CFU/mL, respectively. Koch's postulates were satisfied to confirm the pathogenicity and relationship between *V. parahaemolyticus* and vibriosis (Prescott et al. 1996).

The identity of the bacteria used in challenge tests and after each isolation of Koch's postulates was confirmed using Gram strains, motility tests, characterization of growth on TCBS plates, cytochrome oxidase tests, and API-20NE test strips for Gram-negative, nonfermentative bacteria (API resultant bacteria #7276644). Aseptic techniques were used when working with the bacteria. Waste material was either autoclaved or disinfected with 1% chlorine bleach.

LD_{50} Tests for Litopenaeus vannamei

Vibrio parahaemolyticus was streaked onto TSA + 2.5% NaCl plates from the frozen aliquots as described above. Juvenile animals (5.8 to 8.9 cm and weighing from 1.0 to 4.2 g) were injected intramuscularly near the fourth ventral abdominal segment using a Hamilton syringe with 50 µL of bacterial suspension (ranging from 5×10^3 to 5×10^7 CFU/shrimp) or with 2.5% NaCl buffered with 20 mmol/L HEPES without bacteria as a control. Animals were then placed in 3.5 L, wide-mouth, screw-lid, glass jars with 700 mL of filtered (0.45 µm) artificial seawater (ASW) adjusted to 30 ppt. Lids of the test containers were fitted with tubes for in-

coming air and an air release tube (61 cm) with two cotton plugs to contain *Vibrio* aerosol. Seven animals were placed in each jar with three replicates for each dose. LD_{50} tests were performed under normoxic conditions (155 torr oxygen), with low CO_2 (less than 1 torr) and high pH (pH 7.7–7.9), and mortality was recorded at 2, 4, 8, 12, 24, and 48 hours after injection of *Vibrio*. Water was changed in all jars at 12 and 24 hours after feeding and then when necessary in individual jars (i.e., when the water became cloudy because of shrimp mortality). Animals were fed commercial shrimp food (as above) every 12 hours. The *L. vannamei* LD_{50} test was repeated three times. LD_{50} and confidence intervals for both species were calculated using the EPA Trimmed Spearmann–Karber program (Hamilton et al. 1977).

LD_{50} Tests for Palaemonetes pugio

The methods for the *P. pugio* LD_{50} tests were similar to those mentioned above for *L. vannamei*, with a few exceptions. Because *P. pugio* were smaller (2.1 to 3.4 cm and weighing from 0.2 to 0.4 g), only 5 μL of a saline containing bacteria was injected, and the shrimp were held in smaller test chambers with 400 mL of ASW. Water in all experimental jars was changed once every 24 hours. Animals were fed Marine Tetra Flakes (as above) every 12 hours. The *P. pugio* LD_{50} test was repeated two times with different bacterial concentrations for each (ranging from 2.25×10^1 to 2.25×10^5 CFU/shrimp for test 1, and ranging from 5×10^1 to 5×10^5 CFU/shrimp for test 2).

Challenge Test Design

It was not possible to maintain appropriate levels of oxygen in the jars used for the *L. vannamei* and *P. pugio* LD_{50} tests by directly using Wösthoff gas mixing pumps and individually aerating the jars. This was because of the low output of the pump, the variability in aeration to each jar, and the high oxygen demand of the shrimp. Therefore, a new experimental design was employed for the hypoxic challenge tests for both species. Ten-gallon aquaria were divided into four chambers of equal size to hold the shrimp and one smaller chamber to hold a circulating pump (see below) using Plexiglas drilled with holes to allow water to flow freely among the chambers. Nine L of 30 ppt filtered (0.45 μm) artificial seawater (Crystal Sea marine mix) was added to each tank. A small, submersible pump (Penguin 550) in each experimental tank circulated water among the compartments. Normoxia was maintained by vigorous aeration. Hypoxia was maintained by controlling aeration. The consumption of oxygen by the shrimp lowered the oxygen pressure in the water. Oxygen pressure in the water was monitored using an oxygen electrode and meter (YSI Model 58). Output from the oxygen meter was monitored by a Sable System data acquisition system, which was used to control tank aeration by an air stone at a user-defined setpoint. To control water CO_2 pressures, a Wösthoff gas mixing pump delivered mixtures of CO_2 and nitrogen continuously. The CO_2 and N_2 gas mixture also served to lower the oxygen pressure. At steady state, this system maintained constant oxygen and CO_2 pressures (Fig. 1). Oxygen levels in the chambers remained within 1 torr of the set value.

L. vannamei *Challenge Tests at 45 torr O_2–Normocapnic Hypoxia*

L. vannamei challenge tests were performed under two levels of hypoxia mimicking two different environmental conditions (see Table 1). The first set of tests compared disease susceptibility between animals held under normoxia and animals held under normocapnic (i.e., very low CO_2 pressure) hypoxia with no added CO_2 (treatment 1). This test evaluated the effect of low oxygen only. For these tests, ASW was made hypoxic by bubbling pure N_2 into the first chamber. Gassing the water with N_2 drove off excess CO_2, keeping pH and CO_2 at normoxic levels, with pH 7.8–8.1 and 0.03% CO_2. Normoxia was maintained by bubbling ambient air into the tanks through three air stones.

Using the method described above, juvenile shrimp ranging from 5.7 cm to 9.0 cm (1.0 g to 4.5 g) were injected intramuscularly with 50 μL of bacterial suspension or with 2.5% NaCl buffered with 20 mmol/L HEPES. The bacterial numbers for these tests ranged from 1.8×10^6 CFU/shrimp to 2.25×10^6 CFU/shrimp, which were greater than the previously determined average LD_{50} but were within the 95% confidence interval (Table 2). Nine shrimp with or without injected bacteria were placed in each of the four chambers of the appropriate tanks for a total of 36 animals per tank. Animals were placed randomly in either the hypoxic or normoxic tanks. All four treatments (one per tank) were conducted simultaneously and were counted as one replicate. Mortality was recorded, and dead or moribund animals were removed at 2, 4, 8, 12, 16, 20, 24, 28, 32, 36, 40, 44, and 48 hours after injection challenge. Water was changed in all tanks at 12, 24, and 36 hours, and then whenever necessary in individual tanks. The replacement water for the normocapnic hypoxia treatment was gassed ahead of time to appropriate treatment pressures to avoid a change in oxygen pressure. Animals were fed commercial shrimp food every 12 hours. This challenge test was repeated three times.

L. vannamei *Challenge Tests at 30 torr O_2 + 15.2 torr CO_2–Hypercapnic Hypoxia*

The second set of tests (treatment 2) compared disease susceptibility between animals held under normoxia and animals held under hypercapnic hypoxia at 30 torr oxygen and 15.2 torr CO_2 (4 and 2%, respectively). These tests were conducted as described above (treatment 1); however, the CO_2 and pH were adjusted to mimic hypoxic levels (Table 1). The resulting pH of the hypoxic water was 6.8–7.0. The bacterial concentration used in these tests was 1.125×10^6, which was within the 95% confidence interval previously determined in the LD_{50} tests. This challenge test was repeated three times.

P. pugio *Challenge Tests*

Both of the grass shrimp challenge tests compared disease susceptibility between animals held under normoxia and animals held under hypercapnic hypoxia. These challenge tests were performed under two levels of hypercapnic hypoxia: 45 torr O_2 + 15.2 torr (2%) CO_2 and 30 torr O_2 + 15.2 torr (2%) CO_2. Hypercapnic hypoxia was achieved as described above for both treatments with only the set point for the data acquisition system differing between the two levels of hypoxia (Table 1).

The methods for the *P. pugio* challenge treatments were similar to those mentioned above for the *L. vannamei* treatments, with a few exceptions. For the grass shrimp tests, only 5 μL of a saline containing bacteria was injected, and 10 animals were placed in a chamber for a total of 40 animals per tank. The bacterial concentrations for these tests ranged from 9.10×10^4 to 1.25×10^5 CFU/shrimp. These values were outside of the confidence interval previously determined in the LD_{50} tests because of an experimental error in the original calculation of the confidence intervals. However, because the same bacterial concentration was used for both treatments in a test, the results were unaffected. These challenge tests were each repeated four times.

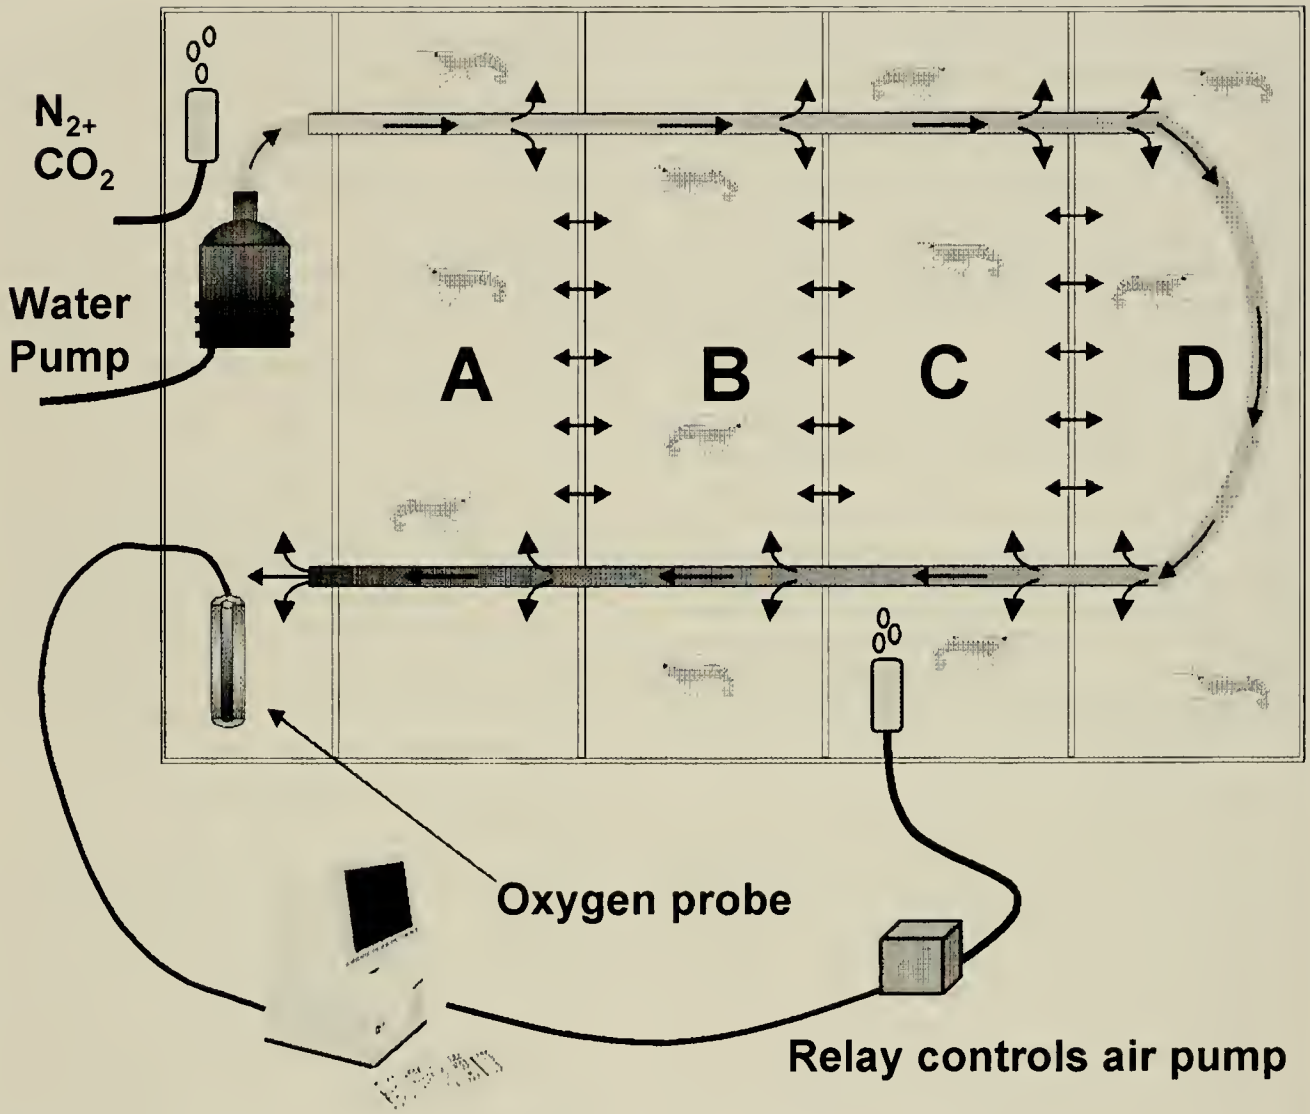

Figure 1. Schematic drawing of the tanks used to hold animals under different gas pressures. Oxygen pressure was measured with an oxygen electrode and adjusted using an air pump controlled by a computer. The infusion of air was opposed by gassing with mixtures of nitrogen and carbon dioxide (depending on the experiment). The tank was divided into compartments, and the water was circulated using a submersible pump.

Statistical Analysis for Challenge Tests

Challenge tests were performed using a full factorial design with bacteria and oxygen as the effect variables. Each challenge test produced four survival curves: normoxia without bacteria, normocapnic hypoxia (hypoxia with very low CO_2) or hypercapnic hypoxia (hypoxia with elevated CO_2) without bacteria (depending on the treatment in question), normoxia plus bacteria and normocapnic hypoxia or hypercapnic hypoxia plus bacteria. Using the statistical program JMP IN (SAS Institute, Inc.), a quadratic polynomial was fitted to each curve to obtain an intercept, response coefficient, and response coefficient^2 for each line. The combined coefficient and coefficient^2 parameters were then analyzed as the response variables in a multivariate analysis of variance (MANOVA) with bacteria, oxygen, and the interaction of bacteria and oxygen (bacteria*oxygen) as the x values. Differences in the coefficient and coefficient^2 revealed differences in the survival rate of shrimp among treatments. The intercepts were not analyzed, because differences in the intercept were artifacts of fitting a quadratic polynomial to a survival curve and did not reveal information about the rate of survival. Four MANOVA tests were run, one for each suite of tests: *L. vannamei* at 45 torr oxygen and <1 torr CO_2, *L. vannamei* at 30 torr oxygen with 15.2 torr CO_2, *P. pugio* at 45 torr oxygen with 15.2 torr CO_2, and *P. pugio* at 30 torr oxygen with 15.2 torr CO_2. Results of the MANOVA tests revealed if oxygen level/CO_2 treatment (normoxia vs. hypoxia), bacteria (absence vs. presence) and/or the interaction of the two (bacteria*oxygen) had a significant effect on ($P < 0.05$) shrimp survival following bacterial challenge. Univariate analysis of variance tests (ANOVAs) were then run to see if the significance found in the MANOVA was attributable to coefficient, coefficient^2, or both.

Total Hemocyte Count

The impact of hypercapnic hypoxia at 30 torr oxygen, 15.2 torr CO_2 and pH 6.9–7.1 on total hemocyte count/mL hemolymph in

TABLE 1.

Water quality variables used in the challenge tests and total hemocyte count (THC) assay.

Ranges of variables observed in nature	0–285	0–38.6	0–14	0.23–35.6	0.03–4.7	6.5–8.3

O_2 and CO_2 are presented several ways for comparison with water quality data in the literature. The following references were used to report the environmental ranges listed for O_2, CO_2, and pH: Breitburg, 1990, Winn and Knott, 1992; Rabalais et al., 1994; Cochran and Burnett, 1996.

Litopenaeus vannamei was measured over the 48 hours to replicate the time period of the challenge tests. At time zero, shrimp were placed randomly in normoxic or hypercapnic hypoxia tanks. Hemolymph from individual adult *L. vannamei* was withdrawn from the ventral sinus at the base of the fourth or fifth walking leg at a specified time point (4, 8, 16, 24, or 48 hours) into a 1.0 mL syringe with a 26-gauge needle. Hemolymph was diluted with an anticoagulant solution (AS) described by Lee et al. (1995): 20% filtered seawater, 30 mmol/L trisodium citrate, 0.1 mmol/L glucose, 26 mmol/L citric acid, 10 mmol/L EDTA at pH 4.6. Total hemocyte counts were performed using a hemocytometer, taking into account the dilution of the hemolymph with AS during bleeding. Twenty shrimp were bled at 4, 16, 24, and 48 h (10 each from normoxia and hypercapnic hypoxia); 22 shrimp were bled at 8 h (11 each from normoxia and hypercapnic hypoxia). Individual shrimp were used only once. Mortality was monitored throughout the experiment.

TABLE 2.

48-Hour LD_{50} values for *Litopenaeus vannamei* and *Palaemonetes pugio* for *Vibrio parahaemolyticus*.

Test	48-hour LD_{50}	95% Confidence Interval
Litopenaeus vannamei		
1	6.04×10^5 CFU/shrimp	2.69×10^5–1.36×10^6
2	1.37×10^6 CFU/shrimp	7.09×10^5–2.64×10^6
3	5.89×10^5 CFU/shrimp	2.90×10^5–1.19×10^6
Mean	8.54×10^5 CFU/shrimp (3.06×10^5/g wet weight)	
Palaemonetes pugio		
1	1.46×10^4 CFU/shrimp	6.22×10^3–3.44×10^4
2	2.16×10^4 CFU/shrimp	2.16×10^4–3.88×10^4
Mean	1.81×10^4tCFU/shrimp (6.08t$\times 10^4$/g wet weight)	

The LD_{50} values are presented as colony forming units (CFU) per shrimp and per gram shrimp wet weight.

A two-way ANOVA test was performed using time, oxygen, and the interaction of time times (*) oxygen as the x values and total hemocyte count (THC) as the response (y) value ($\alpha = 0.05$). An *a posteriori* *t*-test was used to compare means at 48 hours.

RESULTS

LD_{50} Tests

Vibrio parahaemolyticus has dose-response pathogenicity to both *Litopenaeus vannamei* and *Palaemonetes pugio*. Dead or moribund shrimp exhibited signs of Vibriosis, including opaqueness of the abdominal muscle, lethargy, expansion of the chromatophores, and abdominal flexure that peaked at the third abdominal segment (Lightner 1988). LD_{50} values for *L. vannamei* ranged from 5.89×10^5 to 1.37×10^6 CFU per shrimp with an average value of 8.54×10^5 CFU/shrimp (Table 2, $n = 3$). The 95% confidence interval ranged from 2.69×10^5 to 2.64×10^6 CFU/shrimp. Concentrations of bacteria used for the challenge tests remained within these confidence intervals.

LD_{50} values for *P. pugio* were 1.46×10^4 CFU/shrimp and 2.16×10^4 CFU/shrimp, with an average value of 1.81×10^4 CFU/shrimp (Table 2, $n = 2$). The 95% confidence interval ranged from 6.22×10^3 to 3.88×10^4 CFU/shrimp.

Challenge Tests

Control survival

L. vannamei control survival was greater than 77.8, 88.9, and 86.1% in the experiments testing normoxia, normocapnic hypoxia at 45 torr oxygen, and hypercapnic hypoxia at 30 torr oxygen, respectively. *P. pugio* control survival was greater than 92.5, 97.5, and 95% in the experiments testing normoxia, hypercapnic hypoxia at 45 torr oxygen, and hypercapnic hypoxia at 30 torr oxygen, respectively (Fig. 2 and 3). These results show that the levels of hypoxia used were not lethal to either organism.

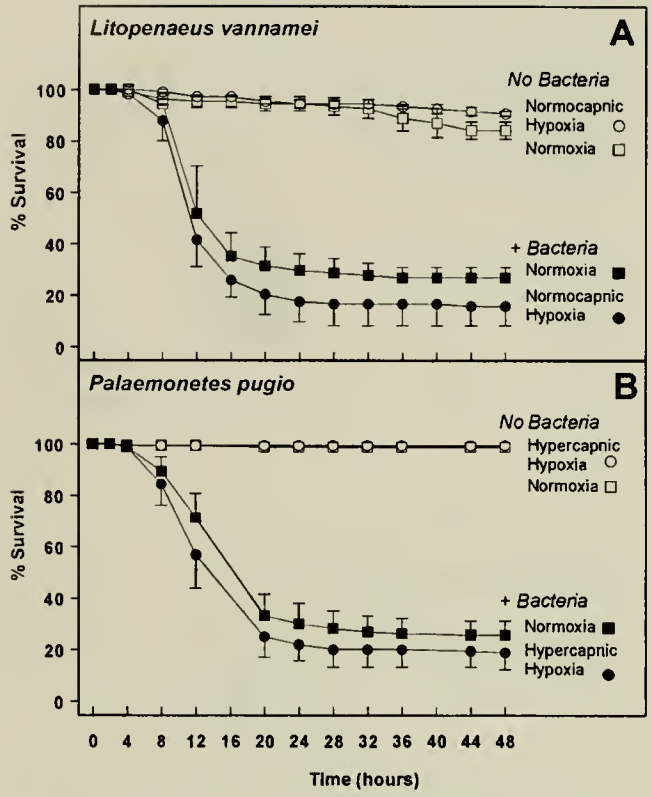

Figure 2. A. *Litopenaeus vannamei* survival following bacterial challenge under normoxia (Po_2 = 150–155 torr, Pco_2 = 0.23 torr, pH 7.6–8.0) and normocapnic hypoxia (Po_2 = 45 torr, Pco_2 = 0.23 torr, pH 7.8–8.1). Shrimp were injected intramuscularly with 50 µL of *Vibrio parahaemolyticus* bacterial suspension (1.8×10^6 CFU/shrimp) or with HEPES buffered 2.5% NaCl for controls. There were 36 shrimp per treatment. Values at each time point are the mean (n = 3 experiments); standard errors are indicated except where the error is small and falls within the width of the datapoint. The effects of oxygen/CO_2 treatment and the interaction of bacteria*oxygen/CO_2 treatment on disease susceptibility were not significant as determined by a MANOVA (P = 0.6478 and P = 0.3594). B. *Palaemonetes pugio* survival following bacterial challenge under normoxia (Po_2 = 150–155 torr, Pco_2 = 0.23 torr, pH 8.0–8.2) and hypercapnic hypoxia (Po_2 = 45 torr, Pco_2 = 15.2 torr, pH 6.9–7.0). Shrimp were injected intramuscularly with 5 µL of *Vibrio parahaemolyticus* bacterial suspension (1.0×10^5 CFU/shrimp) or with HEPES buffered 2.5% NaCl for controls. There were 40 shrimp per treatment. Values at each time point are the mean (n = 4 experiments); standard errors are indicated except where the error is small and falls within the width of the datapoint. The effects of oxygen/CO_2 treatment and the interaction of bacteria*oxygen/CO_2 treatment on disease susceptibility were not significant as determined by a MANOVA (P = 0.7379 and P = 0.7412).

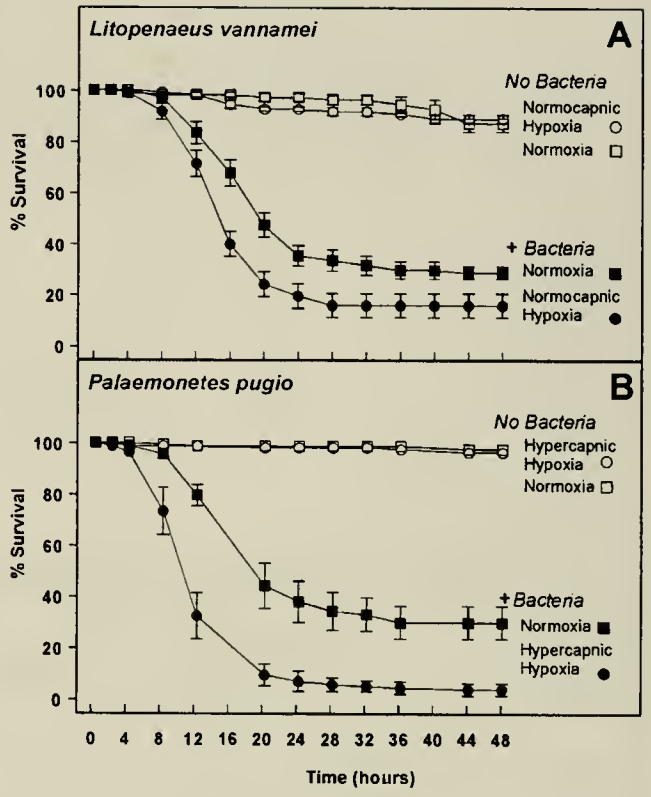

Figure 3. A. *Litopenaeus vannamei* survival following bacterial challenge under normoxia (Po_2 = 150–155 torr, Pco_2 = 0.23 torr, pH 7.6–8.0) and hypercapnic hypoxia (Po_2 = 30 torr, Pco_2 = 15.2 torr, pH 6.8–7.0). Shrimp were injected intramuscularly with 50 µL of *Vibrio parahaemolyticus* bacterial suspension (1.125×10^6 CFU/shrimp) or with HEPES buffered 2.5% NaCl for controls. There were 36 shrimp per treatment. Values at each time point are the mean (n = 3 experiments); standard errors are indicated except where the error is small and falls within the width of the datapoint. The effects of oxygen/CO_2 treatment and the interaction of bacteria*oxygen/CO_2 treatment on survival were significant as determined by a MANOVA (P = 0.0009 and P = 0.0493). Animals held under this level of hypercapnic hypoxia were more susceptible to *Vibrio* challenge than those held under normoxia. B. *Palaemonetes pugio* survival following bacterial challenge under normoxia (Po_2 = 150–155 torr, Pco_2 = 0.23 torr, pH 8.0–8.2) and hypercapnic hypoxia (Po_2 = 30 torr, Pco_2 = 15.2 torr, pH 6.9–7.0). Shrimp were injected intramuscularly with 5 µL of *Vibrio parahaemolyticus* bacterial suspension (9.10×10^4 CFU/shrimp) or with HEPES buffered 2.5% NaCl (controls). There were 40 shrimp per treatment. Values at each time point are the mean (n = 4 experiments); standard errors are indicated except where the error is small and falls within the width of the datapoint. The effects of oxygen/CO_2 treatment and the interaction of bacteria*oxygen/CO_2 treatment on survival were significant as determined by a MANOVA (P = 0.0113 and P = 0.0095). Animals held under this level of hypercapnic hypoxia were more susceptible to *Vibrio* challenge than those held under normoxia.

L. vannamei—normocapnic hypoxia at 45 torr oxygen

These challenge tests examined the effect of moderate hypoxia only (normocapnic hypoxia) without added Co_2 (hypercapnia) on *L. vannamei* survival (Fig. 2A). The effects of oxygen and the interaction of bacteria*oxygen were not significant at Po_2 = 45 torr as determined by a MANOVA (P = 0.6478 and P = 0.3594, respectively). The effect of bacteria alone was significant ($P \leq 0.0001$). Subsequent ANOVA tests revealed that the significance was due to differences in the coefficient and coefficient^2 ($P < 0.0001$ for both). These results indicated that differences in *L. vannamei* survival were attributable to the injection of bacteria over the injection of saline, and not to differences in oxygen levels of the water.

P. pugio—hypercapnic hypoxia at 45 torr oxygen + 15.2 torr (2%) CO_2

These *Vibrio* challenges tested the effect of hypercapnic hypoxia on *P. pugio* survival at a moderate level of hypoxia (45 torr

or 6% O_2) (Fig. 2B). The effects of oxygen/CO_2 treatment and the interaction of bacteria*oxygen/CO_2 treatment were not significant ($P = 0.7379$ and $P = 0.7412$, respectively). The effect of bacteria was significant ($P < 0.0001$) and was attributable to differences in the coefficient and coefficient^2 ($P < 0.0001$ for both, ANOVA). These results show that there was no additional disease susceptibility in *P. pugio* held under this level of hypercapnic hypoxia than those held in normoxic water.

***L. vannamei*—hypercapnic hypoxia at 30 torr oxygen + 15.2 torr (2%) CO_2**

These challenge tests investigated the effects of hypercapnic hypoxia on *L. vannamei* at a more severe level of hypoxia (30 torr or 4% O_2) (Fig. 3A). The effects of oxygen/CO_2 treatment, bacteria, and the interaction of bacteria*oxygen/CO_2 treatment were significant ($P = 0.0009$, $P < 0.0001$ and $P = 0.0493$, respectively) and were attributable to differences in the coefficient and coefficient^2. These results show that *L. vannamei* held under this level of hypercapnic hypoxia experienced a higher rate of mortality from *Vibrio* challenge than shrimp held under normoxic conditions. Average survival at 48 h for animals in normoxia was 28.7 ± 2.4% standard error (SE) versus 15.7 ± 4.6% SE for those in hypercapnic hypoxia.

***P. pugio*—hypercapnic hypoxia at 30 torr oxygen + 15.2 torr (2%) CO_2**

These *Vibrio* challenges tested the effect of hypercapnic hypoxia on *P. pugio* at a more severe level of hypoxia (30 torr or 4% O_2) (Fig. 3B). The effects of oxygen/CO_2 treatment, bacteria, and the interaction of bacteria*oxygen/CO_2 treatment were significant ($P = 0.0113$, $P < 0.0001$, and $P = 0.0095$, respectively) and were attributable to differences in the coefficient and coefficient^2. These results show that *P. pugio* held under this level of hypercapnic hypoxia experienced higher mortality rates from bacterial challenge than animals held under normoxic conditions. Average survival at 48 h for normoxia was 29.4 ± 6.4% SE versus 3.1 ± 2.4% SE for hypercapnic hypoxia.

Total Hemocyte Count

Total hemocyte count significantly decreased in adult *L. vannamei* held under hypercapnic hypoxia when compared to animals held under normoxia over 48 hours. THC/mL was reduced in hypercapnic hypoxia by 60.7, 34.1, 34.3, 40.4 and 16.7% at 4, 8, 16, 24, and 48 hours, respectively, in relation to the normoxia value at the same time point (Fig. 4). A two-way ANOVA indicated that there was a significant effect of oxygen level/CO_2 treatment ($P < 0.0001$) on THC/mL; however, there was no significant effect of time ($P = 0.2907$) or the interaction between time and oxygen/CO_2 treatment ($P = 0.2276$). An *a posteriori* *t*-test used to compare means between oxygen levels at 48 hours revealed that although oxygen level/CO_2 treatment was significant in the two-way ANOVA, THC/mL was not significantly different between the two treatments at 48 hours ($P = 0.3207$, Fig. 4).

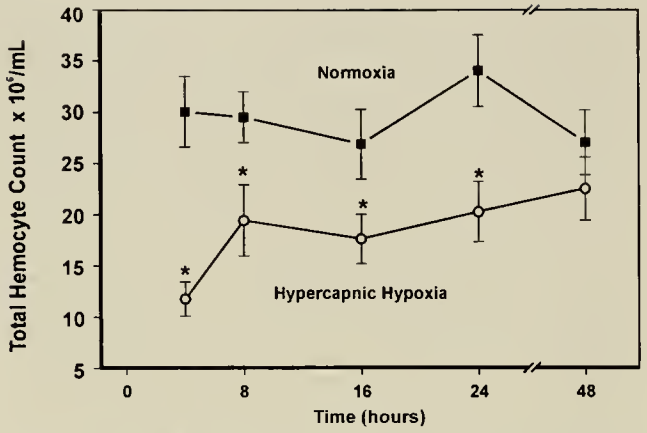

Figure 4. Total hemocyte counts (THC) per mL in *Litopenaeus vannamei* over 48 hours. Shrimp were held under normoxic conditions (closed squares, Po_2 = 150–155 torr, Pco_2 = 0.23 torr, pH 8.0–8.2) or under hypercapnic hypoxic conditions (open circles, Po_2 = 30 torr, Pco_2 = 15.2 torr, pH 6.9–7.1). Individual shrimp were used for each time point and for each test condition (n = 10 shrimp for normoxia and hypercapnic hypoxia at 4, 16, 24, and 48 h, n = 11 shrimp for normoxia and hypercapnic hypoxia at 8 h). A two-way ANOVA indicated that there was a significant effect of oxygen level/CO_2 treatment (P = <0.0001) on THC/mL; however, there was no significant effect of time (P = 0.2907) or the interaction between time and oxygen/CO_2 treatment (P = 0.2276). An *a posteriori* *t*-test revealed that THC/mL was not significantly different between normoxia and hypercapnic hypoxia at 48 hours (P = 0.3207). Values are mean ± standard error (α = 0.05).

DISCUSSION

Estuarine organisms routinely encounter fluctuations in oxygen, carbon dioxide, and pH that may affect their ability to defend against infections. Previous research has linked poor water quality, particularly hypoxia, with increased incidence of infectious disease (Snieszko 1974, Hargis et al. 1989, Landsberg et al. 1998). For example, Landsberg et al. (1998) found that the occurrence of opportunistic protist infections increased in fish subjected to low oxygen conditions. Noga et al. (1994) reported that blue crabs *Callinectes sapidus* collected in areas of the estuary where hypoxia is common, have low serum bacteriostatic activity. This decreased antibacterial activity was correlated with an increase in shell disease. Haley et al. (1967) attributed infections by *Aeromonas liquefaciens* in the threadfin shad *Dorosoma petenense* and the American shad *Alosa sapidissima* to low dissolved oxygen. However, in these field studies, pollutants or other physical factors, such as temperature, may have exacerbated the effects of hypoxia. There have been relatively few studies on the direct effects of hypoxia, hypercapnia, and low pH on disease susceptibility. In the present study, survival following challenge with *Vibrio parahaemolyticus* was depressed in hypercapnic and hypoxic water (Po_2 = 30 torr, Pco_2 = 15.2 torr and pH = 6.8–7.0) in the penaeid shrimp *Litopenaeus vannamei* and in the grass shrimp *Palaemonetes pugio* (Fig. 3A and B). In addition, the THC/mL in *L. vannamei* was reduced under the same conditions (Fig. 4).

The present study used a known pathogenic strain isolated from shrimp with vibriosis. LD_{50} values were reproducible using the same strain and produced consistent mortalities when used in the challenge assays. These are the first reported LD_{50} values for *L. vannamei* and *P. pugio* using *V. parahaemolyticus*.

The 48-h LD_{50} of *V. parahaemolyticus* for *L. vannamei* reported in the present study (Table 2) is similar to the LD_{50} of the same bacterial species for *P. monodon* (3.16×10^5, 95% C.I. 9.60×10^4 to 1.03×10^6 CFU/shrimp). The latter values were calculated from data in Alapide-Tendencia and Dureza (1997) using the trimmed Spearmann–Karber program. Arume (1989) reported LD_{50} values of *Vibrio* isolates to *Litopenaeus stylirostris* ranging from 4.0×10^2 to 3.3×10^4 CFU/g, which is lower than the value

of 3.06×10^5/g wet weight calculated for *L. vannamei* (Table 2). However, the species of *Vibrio* used was not reported. In contrast, *V. parahaemolyticus* had a much higher LD_{50} value for *M. japonicus* juveniles of 4.27×10^7 CFU/shrimp (Vera et al. 1992). This inconsistency in LD_{50} values may be attributable to host specificity and the differences in the size of the animals (Vera et al. 1992, Lee et al. 1996). In addition, virulence of bacteria can vary among strains (Arume 1989, Thune et al. 1993, Wong et al. 1996).

L. vannamei and *P. pugio* were more susceptible to *V. parahaemolyticus* when held under hypercapnic hypoxia at 30 torr oxygen (1.41 mg/L), 15.2 torr (2%) CO_2 and a pH of 6.8 to 7.0 than under normoxia at 150–155 torr oxygen (7.29 mg/L), approximately 0.23 torr CO_2 (0.03%) and a pH of 7.6–8.2 (Figs. 3A and B). This decrease in disease resistance was not attributable to enhanced bacterial growth under these conditions (data not shown). Le Moullac et al. (1999) also found that mortality under hypoxia at 1 mg O_2/L (48%) was significantly greater than control (well-aerated water) mortality (32%) when *L. stylirostris* was challenged with *V. alginolyticus*. However, the levels of CO_2 and the resultant hypoxic pH were not controlled or reported by the investigators. As a result, it is unclear if the animals were subject to hypercapnic hypoxia or to normocapnic hypoxia. In the present study, there was no significant effect on disease susceptibility in *L. vannamei* of normocapnic hypoxia at 45 torr oxygen with less than 1 torr CO_2 or in *P. pugio* under hypercapnic hypoxia at 45 torr oxygen and 15.2 torr CO_2 (Figs. 2A and B).

The level of hypoxia at which disease susceptibility increased (Po_2 = 30 torr) over normoxia in both species may be explained, in part, by the shrimps' critical oxygen tension. The critical oxygen tension for an organism is the oxygen tension below which an organism is unable to maintain its rate of oxygen uptake. Below the critical oxygen tension, organisms may be unable to sustain an internal oxygen level sufficient to defend against infection. Cochran and Burnett (1996) reported a critical Po_2 for *P. pugio* between 30 and 35 torr, which may partly explain differences in susceptibility at 30 torr (1.41 mg O_2/L) and 45 torr oxygen (2.12 mg O_2/L) observed in grass shrimp in this study (Figs. 2B and 3B). On the other hand, Hutcheson et al. (1985) reported a much higher critical Po_2 (approximately 95 torr) for the same species. Nielsen and Hagerman (1998) reported critical Po_2s for *Palaemonetes varians* and *Palaemon adspersus* of 2.4 mg O_2/L (approximately 46 torr) and 2.87 mg O_2/L (approximately 55 torr), respectively, which are both above the highest level of oxygen used in the present experiments. Villarreal et al. (1994) identified a critical Po_2 of 1.3 mg O_2/L (approximately 34 torr) in *L. vannamei*. This value is similar to the value of 1.41 mg O_2/L (30 torr) found to be significant to disease resistance in *L. vannamei* in the present research. In contrast, Rosas et al. (1999) found that juvenile *Litopenaeus setiferus* were oxyregulators down to 4 mg O_2/L (approximately 92 torr), but were oxyconformers between 3 and 2 mg O_2/L (approximately 69 and 46 torr) suggesting that the critical Po_2 lies between those two values. The variability in published critical oxygen pressures may be attributable to many factors including temperature, salinity, activity, molt cycle, size, and experimental technique that can affect the critical Po_2 of a species (Herreid 1980, Dall 1986, Cochran and Burnett 1996).

It is important to note that the oxygen tensions used in the present study were well above the lethal limits reported for these and similar species. Hopkins et al. (1991) reported an oxygen lethal limit of 1 mg O_2/L (approximately 22 torr) for *L. vannamei*. Allan and Maguire (1991) calculated 98-h and 24-h oxygen LC_{50}s for juvenile *P. monodon* of 0.9 mg O_2/L and 0.6 mg O_2/L (approximately 21 and 14 torr), respectively, demonstrating that the duration of the hypoxia also has an effect. Stickle et al. (1989) showed that *F. aztecus* were much more sensitive to low oxygen than *P. pugio*. The 28-day LC_{50} values were 123 torr (5.94 mg O_2/L) for *F. aztecus* and 46 torr (2.22 mg O_2/L) for *P. pugio*. Differences in disease susceptibility between the two species used in the present study (*L. vannamei* and *P. pugio*) could not be compared statistically because of differences in the size of the shrimp and the bacterial challenge dose; however, they exhibited similar responses to the two levels of oxygen tested (Figs. 2 and 3).

As mentioned previously, studies that investigate the effects of hypoxia on estuarine organisms often do not take into account hypercapnia and the low pH that accompanies it (Hutcheson et al. 1985, Seidman and Lawrence 1985, Allan and Maguire 1991, Charmantier et al. 1994, Direkbusarakom and Danayadol 1998, Nielsen and Hagerman 1998, Le Moullac et al. 1999). Nevertheless, these variables may have contributed, in combination or independently, to the decreased disease resistance observed in the present work. Martinez et al. (1998) reported that the lethal dissolved oxygen concentrations for postlarval and juvenile *L. setiferus* are higher under low pH (pH = 6) than under high pH (pH = 8). In addition, McCulloch (1990) found that low pH raised the critical oxygen concentration from 1.54 mg O_2/L at pH 9.0 to 2.08 mg O_2/L at pH 6.5 for *Palaemonetes kadiakensis*. Cochran and Burnett (1996) demonstrated that oxygen uptake was significantly higher at high CO_2 than at low CO_2 in the spot *Leiostomus xanthurus*. Cruz-Neto and Steffensen (1997) reported that hypercapnia increased the critical oxygen concentration from 25 torr to 40–45 torr in the European eel *Anguilla anguilla*. These studies show that hypercapnia can adversely affect hypoxia tolerance.

Total hemocyte count was significantly reduced in *L. vannamei* held under hypercapnic hypoxia (Po_2 = 30 torr, Pco_2 = 15.2 torr, pH 6.8–7.0) when compared to shrimp held under normoxia (Po_2 = 150–155 torr, Pco_2 = 0.23 torr, pH 7.6–8.0) at 4, 8, 16, and 24 h (Fig. 4). Similarly, Le Moullac et al. (1999) found that THC/mL decreased in *L. stylirostris* exposed to hypoxia at 1 mg O_2/L for 24 hours. Alvarez et al. (1989) also noted a reduction in hemocyte concentration in oysters held under two levels of hypoxia (9 and 80 torr oxygen) for 3 days.

Although not measured in the present study, injection of whole bacteria or isolated cell wall components of bacteria and yeast can trigger a decrease in THC/mL in crustaceans (Hauton et al. 1997, Smith et al. 1983, Lorenzon et al. 1999). Using bacterial lipopolysaccharide to suppress circulating THC, Lorenzon et al. (1999) reported threshold lethal limits for THC of 28.9, 32.9, and 15.3% of the initial circulating cells for *P. elegans*, *C. crangon*, and *Squilla mantis*, respectively. These observations suggest that *L. vannamei* and *P. pugio* in the present study that were challenged with bacteria while being held under hypercapnic hypoxia may have experienced a greater decrease in THC than the unchallenged adults held under hypercapnic hypoxia alone. The average total hemocyte count in *L. vannamei* in the present study was reduced to 39.3% of the normoxic average 4 hours after placement in hypercapnic hypoxia (Fig. 4). The combined effects of hypercapnic hypoxia and bacterial injection could reduce cell density in shrimp to a level below the minimum necessary for survival. This is a possible explanation for the increase in mortality in shrimp challenged with bacteria and exposed to hypercapnic hypoxia as compared to animals challenged with bacteria and maintained under normoxia in this study. It is important to note, however, that

dead or moribund animals exhibited signs of vibriosis and that low hemocyte number was not the sole cause of mortality. More likely, the low cell numbers in animals held under hypercapnic hypoxia were insufficient to defend against the bacterial challenge.

The decrease in THC/mL observed in this study may contribute to the increase in mortality rate following bacterial challenge under hypercapnic hypoxia, but many other factors also may play a role. Le Moullac et al. (1999) found that respiratory burst activity, as measured by NBT reduction, decreased in *L. stylirostris* subjected to hypoxia (1 mg O_2/L), but that phenoloxidase (PO) activity increased significantly because of a lower amount of inhibitors regulating the prophenoloxidase system. Direkbusarakom and Danayadol (1998) demonstrated that phagocytosis and bacterial clearance efficiency were reduced in *P. monodon* exposed to 1.8–2.0 mg O_2/L. Although Alvarez et al. (1992) reported that phagocytosis by hemocytes of the eastern oyster *C. virginica* was not affected by hypoxia, Boyd and Burnett (1999) demonstrated that reactive oxygen intermediate (ROI) production by hemocytes was significantly depressed under hypoxia in the same species. Boleza (1999) found that ROI production and bactericidal activity of phagocytes in the mummichog *Fundulus heteroclitis* were suppressed under hypercapnic hypoxia. Comparable studies of cellular and acellular bactericidal factors in *P. vannamei* and *P. pugio* under relevant water quality conditions may clarify the defense mechanisms that are sensitive to dissolved gasses and pH.

The results of the present study show that hypercapnic hypoxia at 30 torr O_2, 15.2 torr CO_2 and a pH range of 6.8 to 7.0 decreases survival following bacterial challenge in both *L. vannamei* and *P. pugio* and decreases total hemocyte count in *L. vannamei* (Fig. 3A and B and 4). This has implications regarding the health of these organisms in both the natural environment and in aquaculture. Diaz and Rosenberg (1995) reported that the occurrence of hypoxia in shallow coastal and estuarine systems is increasing worldwide. Dissolved oxygen monitoring by Summers et al. (1997) in the mid-Atlantic and Gulf of Mexico regions suggests that the extent of hypoxia is often substantially underestimated. Thus, conditions that suppress disease resistance may become more prevalent, which could affect the penaeid shrimp fishery and reduce the density of the ecologically important grass shrimp. In addition, a decrease in THC/mL under hypercapnic hypoxia, as observed in this research (Fig. 4), could result in a decrease in immune function and possibly a reduction of the effectiveness of immunostimulants used in aquaculture to prevent outbreaks of disease (Sung et al. 1991, Sung et al. 1996, Itami et al. 1998, Devaraja et al. 1998, Teunissen et al. 1998). Taken together with the well-recognized importance of water oxygen, dissolved CO_2 and concomitant changes in pH that accompany naturally occurring hypoxia should be carefully monitored and regulated to sustain the wild shrimp fishery and optimize farm production.

ACKNOWLEDGMENTS

The authors thank Dr. Craig Browdy, John Ravenel, and Bill Cox for their help in obtaining juvenile and adult *Litopenaeus vannamei*. Dr. John Fauth helped with statistical analyses; K. Boleza, J. Early, L. Farrelly, and C. Milardo provided technical support. This research was supported by the EPA (Agreement R-826399), Sigma Xi Grants in Aid of Research, the Slocum-Lunz Foundation, and the University of Charleston's Deep Water Fund. This paper is contribution 170 of the Grice Marine Laboratory.

ABSTRACT The geoduck clam, *Panope abrupta*, is a valuable economic resource in Washington State. Prior to the mid 1970s, the levels of paralytic shellfish poisoning (PSP) toxins in Washington State geoducks were not considered by the Washington State Department of Health (WDOH) to be a risk to public health because the viscera were presumed to be discarded. Recent monitoring information indicates that geoducks accumulate high levels of toxins, primarily in the viscera. The purposes of this study were to determine: (1) the seasonal concentration of paralytic shellfish toxins in geoduck clams at two sites and at two depths within each site; (2) the variability of PSP toxin levels among individual clams within each site; (3) the anatomical distribution of toxins; and (4) the correlation between two methods for estimating PSP toxins. From the summer of 1997 through the winter of 1998, 12–24 geoducks were collected biweekly from a shallow (7 m) and a deep (17 m) location in each of two tracts in Puget Sound, Washington: Quartermaster Harbor (QH) and Agate Pass (AP). Geoducks, dissected into siphon, mantle, and visceral portions, were assayed separately using the mouse bioassay (MBA), while only the visceral portions were assayed using the receptor-binding assay (RBA). Results indicated that toxin variability between individual clams was high in the shallow areas, with coefficients of variation (CVs) ranging from 20–98%, and lower in the deep areas (CV = 18–62%). In QH, only geoducks from the shallow water had toxin levels greater than the regulatory level of 80 μg saxitoxinequivalents (STX eq) · 100 g shellfish tissue^{-1}, while all geoducks from AP contained toxin above the regulatory level, with clams from shallow water considerably more toxic than those from deep water. Anatomically, the highest concentrations of PSP toxins were localized in the viscera of geoducks. There was a significant positive correlation between toxin levels measured by the MBA compared to values obtained using the RBA (r^2 = 0.83). The large differences in toxicity between geoducks sampled at different depths and harvest tracts indicate that careful management plans must be designed in order to ensure public health.

INTRODUCTION

General Background

Toxins that cause paralytic shellfish poisoning (PSP) are accumulated by filter-feeding bivalve mollusks when they ingest toxic dinoflagellates from the genus *Alexandrium*. These algae produce the toxins naturally, and the PSP syndrome results from the human consumption of toxic bivalves. Large-scale problems with PSP stem from the extreme difficulty in predicting the timing and extent of dinoflagellate blooms, in turn making it difficult to monitor toxicity in shellfish efficiently (Boesch et al. 1996, Horner et al. 1997). Difficulties also arise because each species of shellfish is unique in the kinetics of uptake and elimination of toxins. In addition, shellfish toxicities do not always coincide with observed toxic algal blooms (Cembella and Shumway 1993, Bricelj and Shumway 1998).

The geoduck clam, *Panope abrupta*, is a valuable economic resource in Washington State, with revenues ranging from $5–7 million annually (Washington State Department of Natural Resources (WDNR), unpublished data, 1997). Recently, the demand from newly developed large markets both domestically and overseas (e.g., Hong Kong, Japan, and Singapore) has sent the price of geoducks up from $1.50 per pound in the late 1980s to a current average price range of $12–14 per pound. Public demand is for whole, live geoducks; the market for shucked or frozen product is very small. While geoducks are one of many species of bivalves known to filter and accumulate toxic dinoflagellates, few data exist that describe PSP toxins in this organism (Shumway 1990; Bricelj and Shumway 1998). The risk of PSP to consumers is therefore increased, which may lead to devaluation of the geoduck as a food item for human consumption if toxic product reaches the market.

Washington's Geoduck Fishery

Prior to the mid 1970s, PSP toxin levels in Washington State geoducks were not considered by the Washington State Department of Health (WDOH) to be a risk to public health because the geoduck viscera were presumed to be discarded. However, we now know that the viscera are consumed by some members of tribal and immigrant communities, who use them in soup (K. Chew, University of Washington pers. comm., 1996, M. Antee, WDOH pers. comm., 1997). In addition, toxic algal blooms are extending into previously benign areas of central and southern Puget Sound (Nishitani and Chew 1988, F. Cox, WDOH pers. comm., 1997), which is leading to unprecedented high levels of PSP toxicity in geoducks and toxicity that lasts well into the winter months, resulting in thousands of dollars of an unharvestable resource. The recent increased demand for geoduck meat is resulting in new tribal and state commercial tracts being opened in some areas of

central and northern Puget Sound where PSP is known to occur (F. Cox, WDOH pers. comm., 1997).

Little information exists regarding PSP toxicity in geoducks. However, recent monitoring programs indicate considerable inter- and intrapopulation variability (F. Cox pers. comm., 1997).

An understanding of the reasons for toxin variability is crucial in designing a regional monitoring and sampling program. The current method used by the WDOH in monitoring and testing for PSP in the geoduck does not account for individual variability in the clams because composite viscera from three clams are tested for toxicity as one sample. In the absence of variability and anatomical distribution information, it is difficult to assess the effectiveness of the current Washington State geoduck monitoring program in protecting public health. This study describes toxin variability in geoducks in relation to water depth and geographical location, thereby providing basic information that can be integrated into future monitoring efforts by the WDOH.

MATERIALS AND METHODS

Sampling

Quartermaster Harbor

Quartermaster Harbor (QH), located between the southern tips of Vashon and Maury Islands (Fig. 1), is currently a prohibited harvest area due to consistent levels of PSP toxicity > 80 μg of saxitoxin equivalents (STXeq)/100 g of tissue (all toxicities are given in micrograms of STXeq/100 g of shellfish tissue) (Nishitani and Chew 1984) and pollution problems resulting from failing septic systems (Washington Department of Fish and Wildlife 1997). There are two tracts in QH, and tract number 10300 was randomly chosen as the study site (Washington Department of Fish and Wildlife 1997).

A shallow and a deep sampling location within this tract were randomly selected. The depth of the shallow location averaged 7 m, adjusted to mean lower low water, and the deep location averaged 17m (mean lower low water). A diver collected 6–14 geoducks within a circular area approximately 27 m in diameter from both depth locations, at 2-wk intervals from June through October 1997.

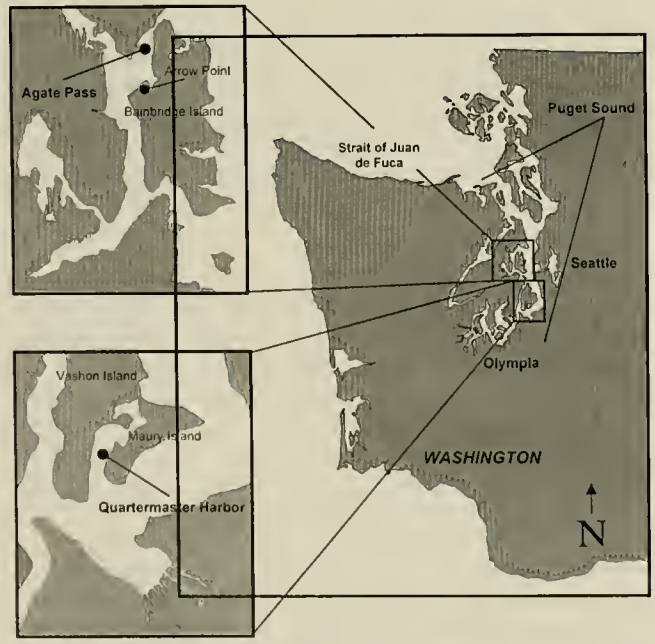

Figure. 1. Map of coastal Washington and Puget Sound showing the study collection sites at AP and QH.

Agate Pass

Tract number 0700 in Agate Pass (AP), located north of Arrow Point on the west side of Bainbridge Island (Fig. 1), is currently a WDOH-approved harvest tract (Washington Department of Fish and Wildlife 1997). A shallow and a deep sampling location were randomly selected in the same manner as in QH. Divers collected geoducks at 2-wk intervals from August 1997 through January 1998. All of the geoducks from deep water consistently came from the same sampling location. In the shallow zone, however, the lack of sufficient numbers of geoducks necessitated a constant lateral shift in collection sites, but all of the shallow sites were within an approximately 300-m section along the shoreline.

Laboratory Determinations

Geoducks were dissected, and toxicities of the siphon, mantle, and visceral portions of individual geoducks were determined by mouse bioassay (MBA) (Association of Official Analytical Chemists 1965). All of the visceral tissue, except the gills, was combined and tested. The gills were saved for future testing, time and funding permitting. Additionally, the visceral portions were tested using the receptor-binding assay (RBA) (Davio and Fontelo 1983, Doucette et al. 1997, Trainer and Poli, 2000). In this assay, nerve terminal membrane from the rat brain, containing sodium channel receptors (STX binding sites) is used to test for the presence of STXeq in a sample. Toxin in the sample displaces radioactively labeled STX from its specific receptor sites, thereby reducing the level of radioactivity in the shellfish sample. Geoduck samples analyzed using this method had toxin levels ranging from 40–1,800 μg (determined by MBA). No samples below the detection limit of the MBA were used.

RESULTS

Anatomical Distribution

The actual toxin levels (given in micrograms of STXeq per 100 g of shellfish tissue) in each of the dissected tissues (siphon, mantle, and viscera) from all clams collected from QH and AP (n = 361), are shown in Figure 2. In QH samples, detectable levels of toxins were found in the mantle portion of three individual clams, but the values were well below the fishery closure level (80 μg) at 46, 47, and 51 μg (Fig. 2B). In AP samples, detectable levels of toxin were found in the mantle portion of seven individual clams and in the siphon portion of nine individual clams (Fig. 2B), however, the values were again well below the fishery closure level. At no time during the study period did the siphon portion from any geoduck show detectable levels of toxicity. All toxicities above the fishery closure level were in the visceral portion only.

Quartermaster Harbor

Shallow Water

Toxin levels above the fishery closure level were detected on all eight sampling dates from June through October, except July 27

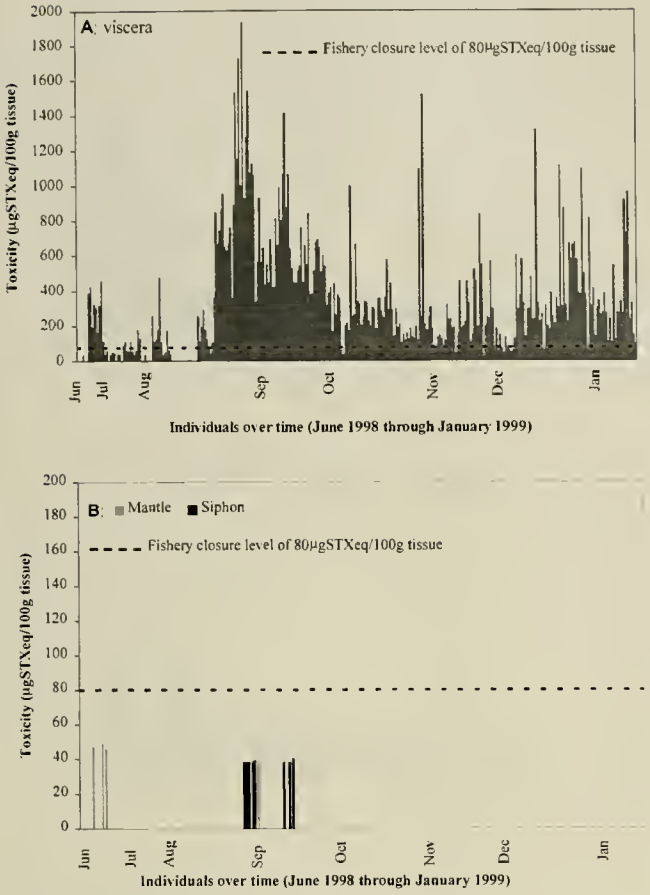

Figure. 2. Toxicity levels in each of the dissected tissues (A = viscera; B = mantle and siphon). Each bar represents an individual geoduck. All geoducks collected from QH and AP during the study are included (n = 361) and are shown in chronological order of collection. The mantle portions of 10 geoducks and the siphon portion of 9 geoducks had detectable levels of toxin but were still below the fishery closure level.

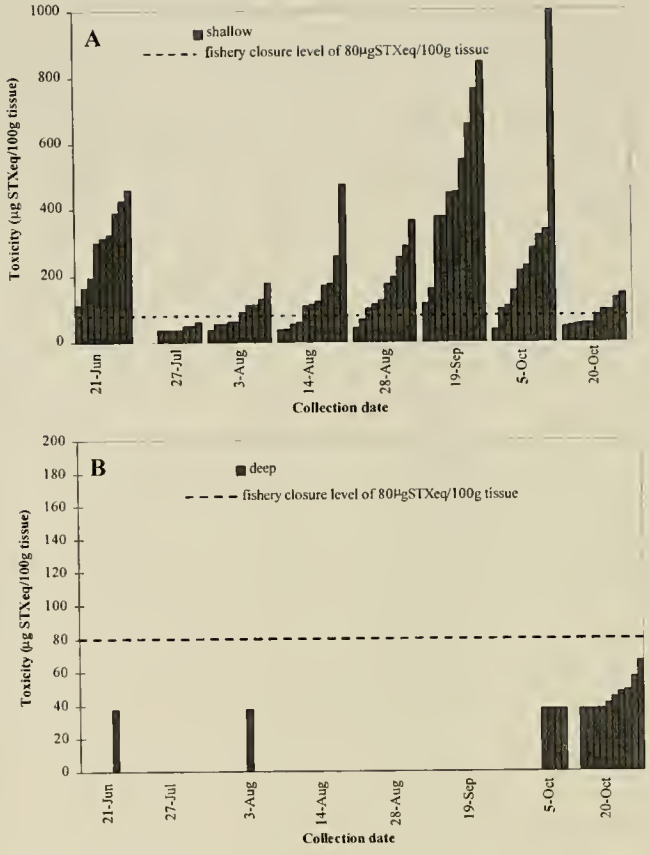

Figure. 3. Toxicity of the viscera in geoducks from the QH collection areas taken from June through October 1997. Each bar represents an individual geoduck. The dashed line indicates the regulatory closure level of 80 μg STXeq/100 g of shellfish tissue. A = shallow; B = deep.

(Fig. 3A). When toxicity was above closure levels, there was a large variation in toxin levels among individual clams. On July 27, variability was low and toxicity levels ranged from 0–61 μg. The largest variation occurred on October 5, with toxin levels ranging from 38–998μg (Table 1).

Deep Water

In QH deep water, toxicity was consistently below the closure level, and values were considerably lower than those observed in the shallow location (Fig. 3B). Toxin levels ranged from nondetectable to 38 μg on all collection dates except October 20, when toxin levels ranged from 0–67 μg. Variability between individuals was low on all sampling dates.

AP

Shallow Water

Toxicities were consistently above the fishery closure level on all 12 collection dates from August through January with the exception of three individual clams, one each on November 12 and 25, and January 6 (Fig. 4A). There was a large variation in toxin levels among individuals on all sampling dates.

Deep Water

Toxicities were consistently above the fishery closure level of 80 μg on most of the 11 collection dates, except December 10 when 50% were below and 50% were above the closure level of 80 μg (Fig. 4B). There was a large variation in toxin levels among individuals on all sampling dates. The largest variation occurred on January 20 with toxicities ranging from 107–545 μg.

Comparison of PSP Detection Methods

Correlations between the MBA and the RBA methods are shown in Figure 5. Figure 5A illustrates the relationship between all samples tested, which ranged from 60–1,700 μg (by MBA). A comparison of the two methods showed a significant positive correlation (r^2 = 0.83). Figure 5B illustrates the relationship between samples with toxicities < 85 μg (by MBA) and demonstrated a significant positive correlation between the two methods (r^2 = 0.55).

DISCUSSION

Variability

The high degree of toxin variability observed among individual geoducks (Figs. 3, 4) is not surprising and has been seen in many other shellfish species. For example, Atlantic surfclams (*Spisula solidissima*) taken off the coast of Maine showed an average coefficient of variation (CV) of 48.6%, and ocean quahogs (*Arctica islandica*) showed a mean CV of 56% (White et al. 1993). Soft-

TABLE 1.

Summary of the variation in levels of PSP toxins among individual geoducks collected from QH and AP during each 1-d collection period, with clams separated by depth.

Area	Sampling Date	*n*	Geoducks with >80 µg of Toxin	Range[a]	Mean ± SD[a]	Pooled SD	CV (%)	Mean CV (%)
QH shallow	June 21	9	9	113–460	298.8 ± 119		40

[a] Values given as micrograms of STXeq/100 g of shellfish tissue.

[b] N/A = not applicable. These values were below detection level and could not be determined.

[c] Only three geoducks had toxicities >38 µg. These values were used to calculate mean, SD, and CV.

[d] Only six geoducks had toxicities >38 µg. These values were used to calculate mean, SD, and CV.

shell clams (*Mya arenaria*) from the Bay of Fundy showed an average CV of 49% (Medcof et al. 1947). Prior to the present study, the only variability information available for geoducks was from an unpublished study in Alaska, where the mean CV for 10 sets of geoducks was 41% (Ketchikan Public Health Laboratories, unpublished data, 1981).

Some variability in PSP toxin levels among individual geoducks can be accounted for by the variability (± 20%) in the MBA test (McFarren 1962). The mean CVs for each set of geoducks (defined by collection area and depth) were close to or greater than twice that in the MBA (38%, 52%, and 53%). However, within sets of geoducks, the CV reached 96% (Table 1), indicating that there was considerable variability between individual geoducks that was not due to an error in the MBA.

Many factors have been suggested to account for variations between individual shellfish, including differences in feeding rates, availability of food due to vertical and horizontal depth gradients, reproductive condition, individual sensitivity to PSP toxins, and variation in body mass (Prakash and Medcof 1962, Nishitani and Chew 1984, Bricelj et al. 1991, Bricelj and Laby 1996, Mackenzie et al. 1996). Much of the variation between individual geoducks within one depth may be attributable to differences in feeding rates (D. Williams, WDNR pers. comm., 1997). At any given time, geoducks are expected to have a 70% "show factor," meaning that only 70% of the population will have their siphons protruding out of the sand but will not necessarily be feeding. This show factor varies with the time of year and could be attributed to changes in water temperature or localized disturbances (e.g., the presence of divers, crabs, siphon-nipping fish, or marine mammals), causing the geoducks to retract their siphons.

The availability of food, often directly related to the behavior of algal cells, is very likely to be the reason for the high degree of

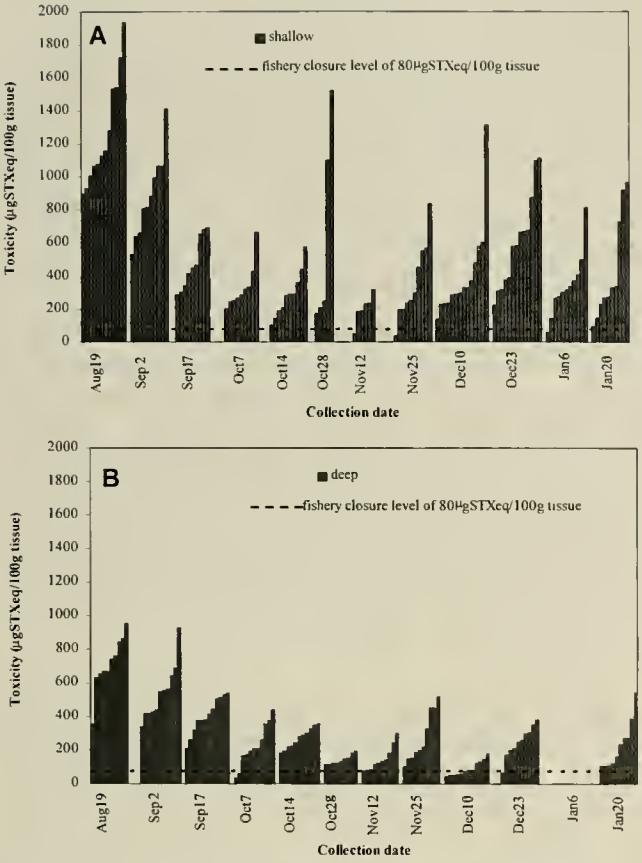

Figure. 4. Toxicity of the viscera in geoducks from the AP collection areas taken from August 1997 through January 1998. Each bar represents an individual geoduck. The dashed line indicates the regulatory closure level of 80 μg STXeq/100 g of shellfish tissue. A = shallow; B = deep.

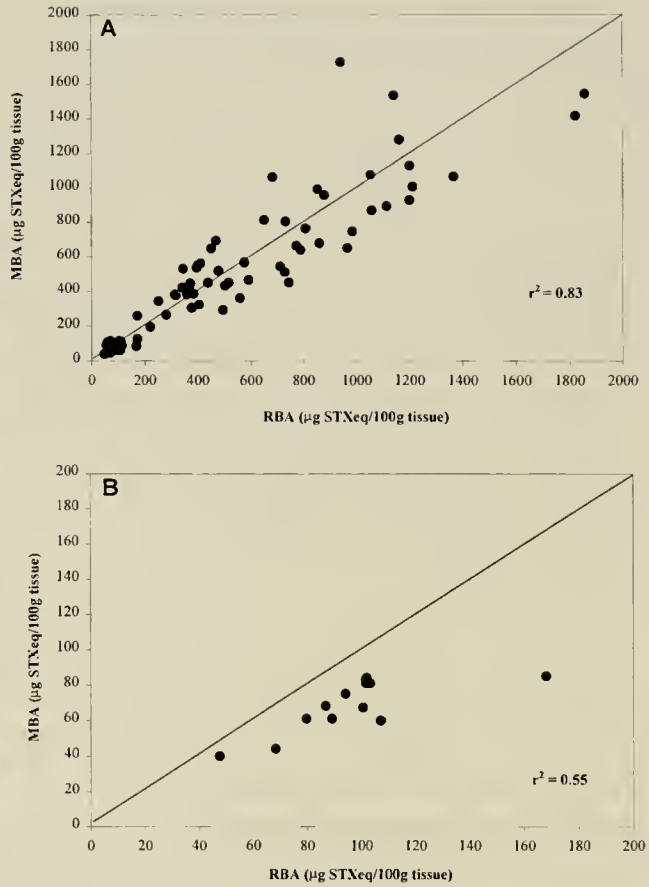

Figure. 5. Correlation between the MBA and the RBA. A = all samples analyzed (n = 73); B = samples with toxin levels between 32 and 85 μg (by MBA, n = 12). The diagonal line represents perfect correlation (r^2 = 1). There was a significant correlation between the two methods: r^2 = 0.83 for all samples and r^2 = 0.55 for samples < 85 μg.

variability between depths (shallow and deep). The toxic *Alexandrium* cells have been found to undergo diel vertical migrations, reaching a maximum depth of 8 m (Nishitani and Chew 1984). The depth of the dinoflagellates also depends on currents and winds, which mix them deeper into the water column. This may explain why the geoducks from the deep water of QH, a shallow, quiet bay without strong currents or vertical mixing, were never over the toxicity closure level, while the ones from the shallow water exhibited high toxin levels (Fig. 3). It is likely that the geoducks from the shallow water were exposed to the toxic dinoflagellates more frequently than the ones from the deep water, thus increasing their overall toxicity. Because AP experiences mixing due to strong and variable currents, with speeds ranging from 0.3–6.6 knots (U.S. Department of Commerce 1973), cells are mixed to greater depth within the water column, making them available for uptake by the geoducks in deeper areas. However, it is likely that the geoducks from the shallow water were exposed to toxic cells more frequently, accounting for their higher overall toxicity.

The difference between collection depths has some implications for the geoduck industry. Currently, harvesting for the market and collection for PSP monitoring occurs primarily in the shallower depths of a harvest tract (D. Winfrey, Puyallup Tribe pers. comm., 1997, D. Williams, WDNR pers. comm., 1998). Geoducks are easier to find, and the divers can collect more clams in a shorter amount of time. In order to accommodate the toxicity differences, harvests could be limited to certain depths during periods of high toxicity (typically in the summer through early winter months). For example, as toxicity levels increase, harvest depths could also be required to increase.

The large difference in overall toxicities between AP and QH is difficult to explain (Figs. 3, 4). It is not unreasonable to suspect that QH would have higher toxicities since it is a "breeding bay" for *A. catenella* (Nishitani and Chew 1984). Breeding bays are defined as certain shallow, protected bays in which strong thermal stratification occurs relatively frequently. In these bays, dense populations of *A. catenella* can develop and become available to the shellfish. However, the AP study area had toxicity levels up to five times (Table 1) those seen in the QH study area, even though AP is an area of strong currents and very little thermal stratification. One explanation for the higher toxicities in AP is the possibility of dinoflagellate cysts in this area, which can be more toxic than motile cells (Dale et al. 1978). Since *A. catenella* forms dormant cysts, it is possible that the geoduck harvesters or the strong currents in AP are stirring up the toxic dormant cysts in the sediments, making them available for uptake by the geoduck and, thereby, accounting for the higher overall toxicities in that area. In addition, QH is a closed harvest area with no diver activity and slow currents, further supporting the explanation for lower overall toxicities.

An additional explanation for higher toxicities in AP could be that motile toxic cells are potentially being exported from a nearby breeding bay. Puget Sound, a fjord with a long, deep main channel, has numerous relatively shallow and often poorly flushed bays, where blooms of *A. catenella* could potentially originate (Horner et al. 1997). The toxic cells, if exported horizontally during periods of reduced turbulence, could cause toxicity levels in shellfish in a nearby area to be several times greater than in the breeding bay itself (Nishitani and Chew 1984).

Individual shellfish within the same sampling population are known to exhibit differential sensitivities to PSP toxins (Bricelj and Laby 1996). This has not been studied in geoducks. Variations in body mass also may have effects on individual toxin accumulation rates. Smaller individual clams can reach equal or higher toxicities than larger individuals collected from the same location (Medcof et al. 1947, Aalvik and Framstad 1981). In this study, there was no relationship between geoduck weight and toxicity level on any date or in any collection area.

Anatomical Distribution

In this study, all PSP toxin levels above closure level were concentrated in the visceral ball in geoducks from all collection sites (Fig. 2). Only the siphon and mantle portions contained an amount of toxin that was below regulatory levels, and, therefore, these were the only portions that would be considered safe to consume during periods of PSP intoxication. This raises the important question of: "How do we protect the public health from the dangers of consuming toxic geoduck viscera?"

The current program used by the WDOH in monitoring for PSP in geoducks could be modified to better protect public health and will be discussed in the next section. Second, geoducks could be shucked and eviscerated prior to being sent to the market. However, 80% of the current market, both domestic and overseas, is for whole, live geoduck, where consumers often pay $12 or more per pound. There is not a large demand for processed geoduck meat (J. Lo, Evergreen International Food Stuff, pers. comm., 1999 L. Elliott, E.C. Phillips and Son, pers. comm., 1999). Typical prices for shucked body meat range from $3–5 per pound, and for neck meat, from $12–24 per pound. These prices depend mainly on the economy and on the availability of whole, live product. In addition, the volume is so small that even the high prices for neck meat do not make up for the overall value of live product. A third solution to the question of how to protect public health is to increase public awareness and education on the dangers of consuming toxic geoduck viscera.

PSP Monitoring

The large difference in toxicity levels between depths and between tracts has implications for the industry and the WDOH. Each harvest area will have to be treated separately when determining sample size and PSP monitoring effort. Perhaps a larger number of samples could be taken in the shallow areas, since most harvest activity occurs in those zones. Because sites vary widely in wind patterns, bathymetry, tidal currents, and turbulence, the extent to which toxicity differences will actually occur may also be expected to vary considerably and can best be tested on a site-by-site basis. It must be noted that the information gained from this study is only applicable to the specific study sites. However, generalizations, such as high variability between individual geoducks, can be made to other populations.

Assay Comparison

In this study, the RBA overestimated MBA results by an average of 22.8%. Doucette et al. (1997) found that the RBA agreed very closely with MBA results from one laboratory but tended to overestimate those originating from a second source. The reasons for overestimation are unclear. Differences are expected, given that the RBA is performed on a static system and the MBA is performed on a dynamic system (live mice). Resulting toxicities can be affected by metabolic changes in the mice. Other work has shown that the MBA is known to underestimate actual toxicity by as much as 60% at lower toxicity levels (McFarren 1957, Park et al. 1986). Therefore, the lower levels of toxicity obtained by MBA in this study could have been underestimated by as much as 60%, accounting for most of the overestimation by the RBA. Variability at low toxicity levels in the MBA is affected by many factors, including salt content during sample preparation, pH, and storage (McFarren 1957, Park et al. 1986). Last, after initial sample preparation, some degradation of the low-toxicity compounds B1 and B2 (N-sulfocarbamoyl toxins) to the nonsulfated carbamate toxins, STX and neosaxitoxin, could have occurred, resulting in increased toxicity by the RBA (Cembella et al. 1993).

The overestimation of toxicity levels by the RBA has implications for the industry and the WDOH if this were chosen as the approved method of toxin detection. At very low levels of toxicity (near the regulatory level of 80 μg), the geoduck fishery would be closed to harvest more often. However, the RBA could prove to be a useful tool in prescreening shellfish for PSP toxins. It also may have applications as a diagnostic tool in suspected cases of STX poisoning in humans and marine animals. Overall, the two methods were in very good agreement, as confirmed by a significant correlation coefficient (r^2 = 0.83 for all samples, r^2 = 0.55 for samples < 85 μg). The assay warrants consideration as a rapid, reliable, and cost-effective alternative to the MBA.

CONCLUSIONS

1. Geoducks collected at shallow depths in both tracts were more variable in levels of toxicity and were more toxic than geoducks from the deeper waters.
2. Toxicity levels in the shallow AP area were about two times those in the shallow QH area. Toxicities in the deep AP area were about five times those in the deep QH area. In the deep AP area, toxicity levels were almost always well above the closure level, while those in the deep QH area were always below closure level.
3. Results indicate substantial variability in toxicity levels among individual geoducks within a small population. It appears that the overall variability among geoducks in both shallow areas can be generally characterized as having a CV of about 53%, and in the AP deep area having a CV of 38%. In the QH deep area, the CV could not be measured because of an insufficient numbers of geoducks with detectable levels of toxicity.
4. All toxin levels recorded above the regulatory closure level (80 μg STXeq/100 g of tissue) were in the viscera only.
5. At low levels of toxicity (< 85 μg STXeq/100 g of tissue), the RBA overestimated the MBA. However, most of the overestimation can be accounted for by the inherent variability in the MBA and its tendency to underestimate low levels of toxicity by as much as 60%. Overall, the two

methods had a high degree of correlation (r^2 = 0.83 for all samples, r^2 = 0.55 for samples < 85 μg STXeq/100 g of tissue).

The results of this research have implications for the geoduck industry and public health agencies. The following recommendations can be implemented to improve geoduck sampling and analysis.

1. Due to the toxicity differences in harvest depth, the collection of geoducks during the PSP season could be limited to the deeper areas of a harvest tract to avoid fishery closures.
2. Farmers interested in culturing subtidal geoducks should consider doing so in deeper areas to avoid the high toxicities found in the shallow areas.
3. From a risk-management standpoint, a larger number of samples collected from shallow areas would have to be analyzed to reduce the risk of PSP intoxication in consumers.
4. The toxicity difference between tracts implies that the physical aspects of each tract may have to be considered when sampling and monitoring for PSP in geoducks.
5. Geoducks should be tested for PSP on an individual basis rather than as a composite of three samples, to account for the high degree of individual variability seen in this study.
6. The viscera could be immediately removed and discarded prior to consumption of the siphon and mantle portions, which have been shown to be safe to consume even during times when viscera are highly toxic.

VIABILITY OF THE TOXIC DINOFLAGELLATE *PROROCENTRUM LIMA* FOLLOWING INGESTION AND GUT PASSAGE IN THE BAY SCALLOP *ARGOPECTEN IRRADIANS*

ANDREW G. BAUDER AND ALLAN D. CEMBELLA

ABSTRACT Bay scallops *Argopecten irradians* were fed cells of the epibenthic dinoflagellate *Prorocentrum lima*, a known producer of diarrhetic shellfish poisoning (DSP) toxins, in controlled microcosms in the laboratory. Examination of scallop fecal ribbons revealed that ingested *P. lima* cells were capable of survival and cell division following passage through the scallop gut. This implies that viable *P. lima* cells released via fecal deposition from transferred stock may be capable of long-term survival and growth. The ability of this dinoflagellate to adapt and survive in a wide variety of benthic environments coupled with circumstantial evidence of its involvement in toxic events, suggests that release of viable cells poses a risk of increasing the geographical range of this species, with negative consequences for the shellfish industry.

KEY WORDS: *Argopecten*, bay scallop, *Prorocentrum*, dinoflagellate, DSP toxins

INTRODUCTION

Contamination of bivalve mollusks by diarrhetic shellfish poisoning (DSP) toxins poses an economic threat for shellfish harvesters in many parts of the world (Shumway 1990). Dinoflagellates recognized as producers of DSP toxins include several planktonic *Dinophysis* species (Reguera et al. 1993, Yasumoto 1990) and a few benthic/epibenthic species of *Prorocentrum* (McLachlan et al. 1994). Although species of *Dinophysis* are implicated most frequently as the causative organisms of DSP events, there is growing evidence that *Prorocentrum lima* (Ehrenberg) Dodge is the cause of DSP toxicity at aquaculture sites in eastern Nova Scotia (Jackson et al. 1993, Lawrence et al. 1998).

The possibility of toxigenic dinoflagellate cells surviving passage through the digestive tracts of shellfish is an area of special concern for growers. After contamination by toxic dinoflagellates, shellfish stocks may be transferred to "clean" waters to depurate (Haamer et al. 1990, Silvert and Cembella 1995). If live dinoflagellate cells are released into pristine waters via fecal deposition from newly transferred stock, they may divide and populate the transfer site. Furthermore, even in the absence of measurable toxicity, there is a possibility that viable cells could be inadvertently transferred to new sites via the expanding trade in cultured shellfish, especially when the apparent increase in the frequency and variety of harmful algal blooms is considered (Hallegraeff 1993). Studies demonstrating the survival of vegetative cells and pellicular cysts of the dinoflagellate *Alexandrium tamarense* (Scarratt et al. 1993), *A. fundyense* (Bricelj et al. 1993), and *A. minutum* (Laabir and Gentien 1999), producers of paralytic shellfish poisoning (PSP) toxins, in mussel (*Mytilus edulis*) and oyster (*Crassostrea gigas*) feces have warned that such a process could serve as a potential seed source for subsequent dinoflagellate blooms.

Recent studies have demonstrated that DSP toxins are accumulated in tissues of the mussel *M. edulis* (Pillet et al. 1995) and the bay scallop *Argopecten irradians* (Bauder et al. 1996) when toxic *P. lima* cells are ingested. However, the fate of undigested cells is also of interest, because no studies have examined whether dinoflagellates known to produce DSP toxins can survive gut passage in bivalves. The objective of the present study was to investigate the likelihood of survival of *P. lima* cells following ingestion by *A. irradians*.

METHODS

Bay scallops *Argopecten irradians* (mean shell height = 38 ± 4 mm), were exposed to toxigenic *Prorocentrum lima* (strain Pa) at a constant density of 10^5 cells L^{-1} for 13 d in an 80-L aquarium at 17 °C (Bauder 1997). Cells were kept in suspension using two recirculating pumps mounted on the aquarium. Scallops were subsequently transferred to another aquarium and depurated for 1 week on a nontoxic diet of the diatom *Thalassiosira weissflogii* (ACTIN, CCMP #1336). During the depuration period, the entire volume of the aquarium was replaced each day with 1 μm-filtered seawater to reduce the possibility of scallops re-ingesting fecal ribbon contents.

Fecal ribbons produced by scallops after 12 days of exposure to *P. lima* cells were gently removed from the aquarium by a Pasteur pipette and rinsed by allowing the feces to settle in 20 mL scintillation vials containing 1-μm filtered seawater. Feces were then transferred to another vial containing filtered seawater and kept on ice.

Viability of *P. lima* cells within fecal ribbons was determined by inoculating triplicate samples of intact or disrupted (vortex-mixed for 30s) fecal ribbons in flasks containing 200 mL of K-medium (Keller et al. 1985). A 5 mL sample of *P. lima* stock culture was also inoculated in triplicate as a control for comparison of cell division rates. Cultures were grown on a 14:10 L:D photocycle at a photon flux density of 90 μmol m^{-2} s^{-1} at 17 °C. Cell concentrations in each of the flasks were determined every 7days over a 4-week period by enumerating 5 mL subsamples in a 0.1 mL Palmer–Maloney chamber under phase-contrast microscopy (100×). Division rates were calculated according to the formula of Guillard (1973).

Fecal ribbons produced by scallops during exposure to *P. lima* cells and during the depuration period were photographed at up to 1000× magnification under Nomarsky interference microscopy. *Prorocentrum lima* cells in the feces were examined for such obvious characteristics as thecal integrity and cell motility.

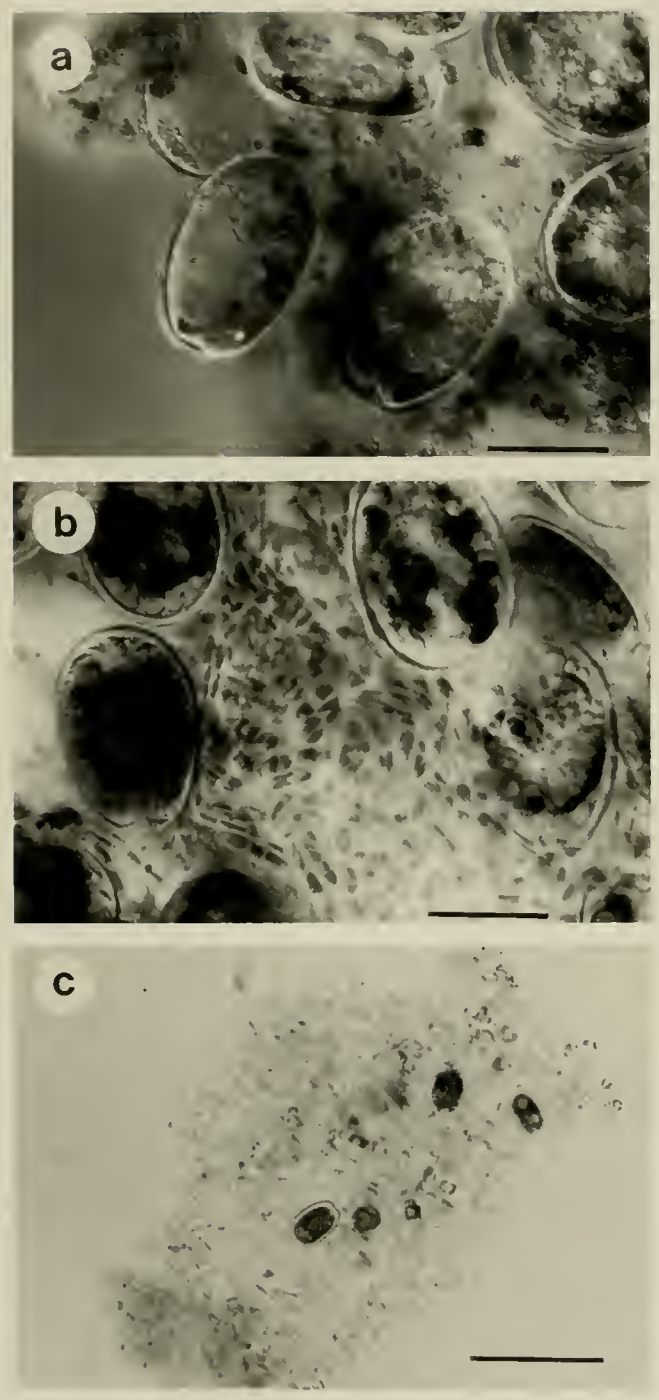

Figure 1. Nomarsky interference photomicrographs of fecal ribbons produced by *Argopecten irradians* after (a) 2 days and (b) 12 days exposure to *Prorocentrum lima*, and after (c) 3 days of depuration on a diet of *Thalassioisra weissflogii*. Scale bars = 20 µm (a, b) and 100 µm (c).

RESULTS

Microscopic examination of fecal samples revealed that intact and motile *Prorocentrum lima* cells were abundant in scallop fecal ribbons throughout the exposure period. Cells were frequently swimming by flagellae within the fecal ribbons, as well as along the exterior margins of the ribbons, suggesting that these cells had recently migrated from the feces into the surrounding medium. Evidence that some *P. lima* cells were digested during passage through the scallop gut was provided by the presence of *P. lima* thecal fragments and free starch granules within the feces. A greater proportion of digested *P. lima* cells within fecal ribbons was observed at the beginning of the exposure period than during the latter portion (Fig. 1).

Live *P. lima* cells were observed by microscopy in fecal ribbons produced by scallops until the fourth day of depuration (Fig 1c). Pigments and thecal fragments derived from digested *Thalassiosira weissflogii* cells were abundant in fecal ribbons; however, unlike *P. lima* cells, very few of these diatom cells were intact.

Mean division rates (k) calculated over exponential growth phase of *P. lima* cells contained in fecal ribbons were 0.26 d^{-1} (SD = 0.03) and 0.21 d^{-1} (SD = 0.04) for disrupted and undisrupted fecal ribbons, respectively, indicating that the cells were viable and able to divide at rates comparable (ANOVA, $P > 0.05$) to those of *P. lima* cultures (k = 0.24 d^{-1}, SD = 0.01) when inoculated into growth medium (Fig. 2). Similar division rates for cells inoculated from intact and dispersed fecal ribbons show that *P. lima* cells were capable of freeing themselves from the fecal ribbons.

DISCUSSION

The present study is the first to demonstrate the survival of DSP-toxigenic algal cells in bivalve fecal ribbons. Although Mackenzie (1998) found large numbers of intact thecae of another DSP toxin producer, *Dinophysis acuta*, in fecal pellets deposited by the mussel *Perna canaliculus*, viable cells were not observed. It was further noted that mussel stomach fluids rapidly lysed *D. acuta* cells.

In a study demonstrating that PSP toxin-producing *Alexandrium* cells could survive and reproduce following passage

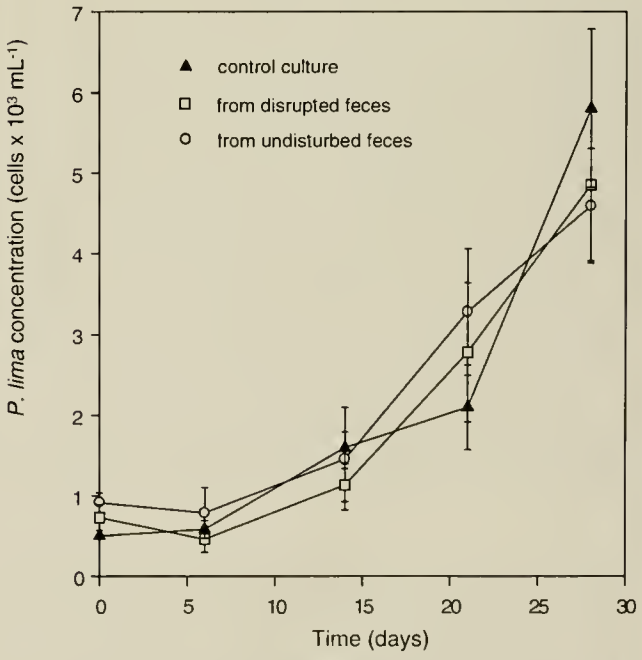

Figure 2. Growth of *Prorocentrum lima* cells in K-medium. Inoculated from either *P. lima* culture or fecal ribbons of *Argopecten irradians* following ingestion of *P. lima* cells (undisturbed and disrupted fecal ribbons). Error bars: ± 1 standard deviation, $n = 3$.

through the gut of *Mytilus edulis*. Scarratt et al. (1993) reported that after 3.9 h of depuration, almost all of the fecal ribbons were free of *Alexandrium* cells. These authors suggested that 12 h of purging should be sufficient to rid mussels of toxic cells before transferring stock to new waters. Passage of *Prorocentrum lima* cells in bay scallop guts occurred over a much longer time scale, as demonstrated by the presence of live cells in fecal ribbons even after 3 days of depuration, during which the scallops were continually ingesting *Thalassiosira weissflogii* cells.

Bomber et al. (1988) reported that live *P. lima* cells have been found attached to the viscera of tropical fish and argued that the ability of these cells to survive in fish viscera for extended periods represents an important system of dispersal for this species. Similarly, the slow passage of *P. lima* cells in scallop guts represents a potential mechanism of cell dispersal to new aquaculture and wild harvest sites via shellfish stock transfer.

Although *P. lima* cells released in scallop feces have been shown by this study to be viable in culture, the analogous situation at a shellfish aquaculture site must be addressed. In the absence of a strong vertical mixing component, bivalve fecal ribbons containing *P. lima* cells would rapidly sink out of the water column to the benthic environment below the site. For many species of photosynthetic microalgae, this environment would be unfavorable for survival, because it is characterized by low irradiance and temperatures as well as enhanced levels of ammonium and organic detritus derived from shellfish waste products. However, observations consistently indicate that *P. lima* is a very robust species, well suited to a wide variety of benthic environments.

Bomber et al. (1985) observed survival of *P. lima* among benthic detritus in unaltered seawater for up to 6 months. Similarly, McLachlan et al. (1994) reported that *P. lima* cultures can be kept in the same culture medium for over 6 months and that the cells are capable of long-term survival at temperatures of 0 °C. The cellulose theca of *P. lima* is extremely resistant to physical disruption; overwintering stages are primarily in the form of vegetative cells, rather than cysts. This demonstrates the potential for this species to be introduced and established at sites that experience low winter water temperatures. Exposure to high concentrations of ammonium and other organic nutrients from shellfish excretory products may even be a benefit to *P. lima* populations. Carlson and Tindall (1985) noted that *P. lima* is associated with natural habitats characterized by high nitrogen concentrations. Bauder et al. (unpubl. data) observed that batch cultures of *P. lima* grew well in enriched natural seawater (K-medium) with augmented ammonium concentrations as high as 300 μM.

The evidence provided in this study of *P. lima* viability following gut passage in scallops, coupled with the broad ecophysiological tolerances of this dinoflagellate strongly suggest that *P. lima* cells released into the waters of a shellfish aquaculture site via fecal deposition from transferred stock would have a high probability of long-term survival and growth.

ABSTRACT This study concerns the development and use of an immunological method for rapid identification of bivalve larvae in plankton samples. Protein extracts from larvae and adults of various bivalves were prepared and analyzed according to molecular biology techniques (electrophoresis and transfer) for the purpose of species identification. Protein extracts of larvae and adults of *Pecten maximus* induced the production of polyclonal rabbit antibody directed against this scallop. The specificity of these sera was tested by an immunological transfer method (Western blotting). The antibodies selected were used directly on plankton samples. The antigen–antibody pair and, thus, the larvae of *P. maximus* were revealed by secondary markers (colorimetric, fluorescent, and magnetic). The use of such markers is considered for routine work, especially in shellfish farming and marine ecology.

KEY WORDS: Bivalve larvae, antibody, protein recognition

INTRODUCTION

Most benthic marine invertebrates (e.g., the scallop *Pecten maximus*) have a life cycle divided into two distinct stages, benthic for adults and planktonic for larvae, which are closely related in terms of shellfish farming and management. Although most macroscopic species of marine invertebrates have been thoroughly studied, their microscopic stages have often been ignored, particularly because of a lack of suitable "tools" and materials to study organisms under 250 μm in size living in three-dimensional (3-D) space.

Several methods have been used to identify bivalve larvae from plankton samples. One, based on analysis of prodissoconch shape, is applicable only to such families as Anomiidae and Ostreidae (Chanley and Andrews 1971, Le Pennec 1978, Loosanoff et al. 1966). Another limited to the study of hinge characteristics (Rees 1950) was subsequently used with scanning electron microscopy (SEM), enabling different species of bivalves to be reared in the laboratory, particularly during larval and postlarval periods (Le Pennec 1978, Lutz et al. 1982). Unfortunately, this method is time-consuming and difficult to implement, especially for investigation of young stages of bivalve larvae in plankton. Herrera and Cordoba (1981) used immunochemistry to identify bivalve species and suggested that this technique could be applied to taxonomic classification of these organisms in their early stages of development.

In general, immunological techniques allow precise recognition of certain antigens, so that the identification of antigens specific for a given species is possible. This method has not only been applied classically to the medical diagnosis of such pathogenic agents as bacteria and viruses, but also in ecology to determine the diets of different marine vertebrates (Pierce et al. 1990). In fact, the suggestion of Herrera and Cordoba (1981) was not further pursued until the beginning of the 1990s, when Hu et al. (1992) identified bivalve larvae (*Crassostrea gigas*) using protein separation by electrophoresis. A year later, Demers et al. (1993) developed an immunological technique based on monoclonal antibodies to detect the larvae of Pectinidae (*Placopecten magellanicus*) in the sea. Unfortunately, the data provided by these authors were imprecise, which led us to design a new immunological protocol, but not based on monoclonal antibodies. Our basic notion is that molecular modifications probably occur during the different stages of larval life and may block the binding of monoclonal antibodies to their epitope. To avoid this phenomenon, it is preferable to multiply the number of epitope recognized. Thus, our purpose was to develop an immunolabeling process based on the use of polyclonal antibodies that could recognize bivalve larvae in the wild.

MATERIALS AND METHODS

Larval Samples from Hatcheries

The preparation of monospecific antigens to produce "polyclonal" antibodies required the use of batches of larvae of the same species produced by stockbreeding. Several species from three different families (Pectinidae, Ostreidae, and Veneridae) were available. The larvae were collected directly in rearing tanks, washed three times with phosphate-buffered saline (PBS), freeze-dried for 3 h in a Maxi-Dry Coldfinger (FTS ® System Inc. Model FD-4.5-90) and then stored at − 80 °C. *P. maximus* larvae were obtained from a private fishermen's cooperative at Tinduff (Brittany, France) and from the IFREMER experimental bivalve hatchery in Argenton (Brittany, France); *Ostrea edulis* larvae from the IFREMER experimental genetics laboratory at La Tremblade (Charente-Maritime, France); *C. gigas* larvae from the IFREMER hatchery in Argenton and from SATMAR (Socété Atlantique de Mariculture, Gatteville-Phare, Normandy, France); and *Tapes decussatus* larvae from SATMAR and from Tinamenor SA Cantabrica (Spain). All larval stages were represented, from the D-shaped one to pediveliger.

Plankton Samples

Plankton samples were collected in the Bay of Brest using a high-discharge submersible pump, as described by Tremblay and Sinclair (1990). Seawater flowed downward through a 25-cm diameter sieve composed of two nets (the upper one with 300-μm mesh to remove the largest elements, and the lower one with

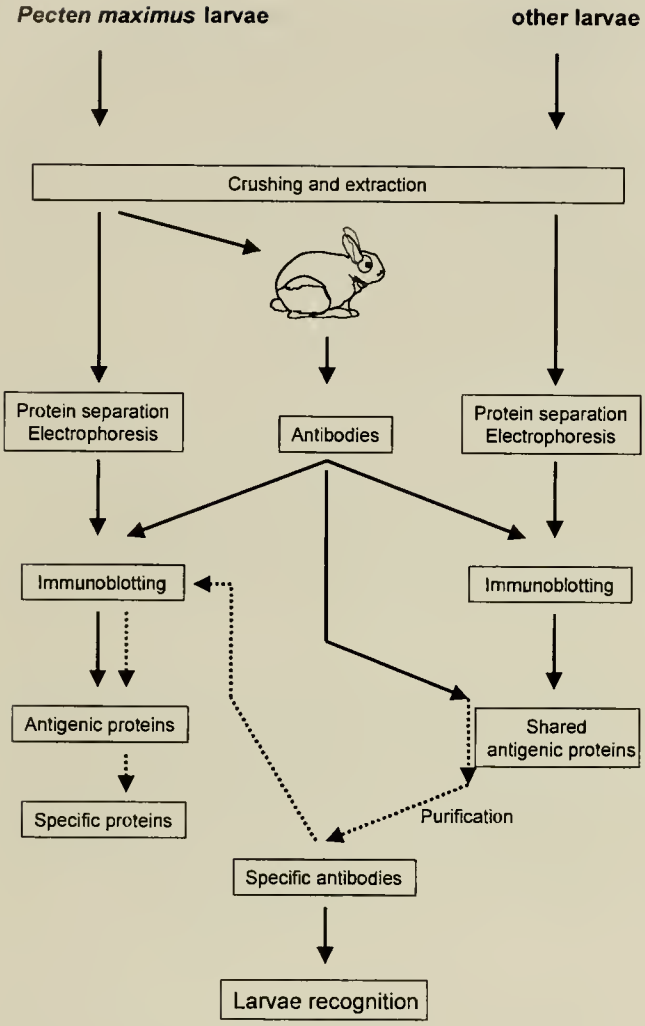

Figure 1. Protocol.

50-μm mesh to retain the plankton fraction likely to contain bivalve larvae). The mesh sizes were suitable for trapping most of the largest bivalve larvae during pelagic development in experimental conditions. Once collected, the plankton was quickly washed with distilled water and stored at 4 °C in 50 mL of 70 ° alcohol.

Adult Bivalves

Thirty or more 3-year old individuals of *P. maximus* and *C. gigas* were collected by scuba diving in the Bay of Brest for subsequent protein extraction.

Protein Extraction

Protein extracts were prepared for electrophoretic analysis and immunisation of New Zealand rabbits. Except for the crushing method, the same protocol was applied to larvae and adults. Larvae were either sonicated or processed with a French press (Bioblock Scientific G 43221); whereas, adults required a precrushing step to break fibres before sonication or French press extraction.

Protocol for Larvae

1. Ultrasonic extraction. Larvae were progressively thawed from – 80 °C in a cold room to 4 °C and then covered with 10 mL of phenol and 10 mL of distilled water before sonication at 50 Hz with a Branson sonifier. To avoid heating, they were subjected to 10 1-second sonication sequences and then placed momentarily (a few seconds) in an ice bath before the next sonication series. This procedure was repeated 12 times to crush most of the shells and suspend the organic matter. The entire solution was stirred for 15 min in a water bath maintained at 68 °C and then cooled to below 10 °C in an ice bath. After centrifugation for 45 min at 4,000 × *g* (4 °C), the pellet was suspended in 4 mL of water at 0.2% in sodium dodecyl sulphate (SDS) containing 1 mmol of phenylmethane sulphonylfluoride (PMSF) and ethylenediamine tetraacetate (EDTA) (proteolysis inhibitors). This solution was dialysed for 2 days in PBS 7.2 containing 0.02% sodium azide, homogenized with a vortex in 8 mL of cold methanol at 0 °C, 4 mL of chloroform and 3 mL of distilled water and then centrifuged for 15 min. at 4,000 × *g*. Once the aqueous phase had been removed, the protein interface was collected and rinsed with 2 mL of distilled water before centrifugation for 15 min. at 4,000 °× *g*. The resulting pellet was dissolved in 2 mL of water before the next centrifugation. This procedure was repeated three times. The final pellet was dissolved in 5 mL of distilled water with 0.2% SDS and 1 mmol PMSF and EDTA to constitute the larval protein extract.

2. French press extraction. The French press was used only to prepare larval extracts. Two millilitres of freeze-dried larvae were suspended in 15 mL of a chloroform:methanol mixture (2 v:1 v), to which 5 mL of distilled water were added before the final solution was poured into the previously cooled 50-mL cylinder of the French press. After 16 metric tons of pressure were applied by a hydraulic press for at least 2 min, the liquid was stirred for 2 min at room temperature and centrifuged for 15 min at 4,000 × *g* at 4 °C. As noted above, the protein extract was contained in the interface layer and required further washing with water.

Protocol for Adults

Because of the large amount of organic matter studied in adult as compared to larval tissues, the tools used for preparation of extracts differed. The tissues were mixed for 2 min at full speed with a kitchen mixer (Moulinex), and the resulting homogenates were treated as for larvae. In the case of scallops, some specific extracts (muscle, mantle, gill, gonad, and digestive gland) were also prepared.

Protein Titration

Protein concentration was determined by a protein-dye binding assay with bovine serum albumin (BSA) as standard (Protein Assay and DC Protein Assay kits, Biorad, ref. 500-0001 and 500-0111, respectively).

Electrophoresis and Blotting

The various protein extracts were partitioned by SDS-polyacrylamide gel electrophoresis (PAGE) (Laemmli 1970). The blotting technique applied was initially designed by Towbin et al. (1979), improved by Kyhse-Andersen (1984), who used a semidry system, and finally modified by Gitton et al. (1992).

Electrophoresis

Aliquots (5 μg) of bivalve proteins were diluted in sample buffer (1:4, v:v) containing 5.5% SDS, 5.5% glycerol, and 1.7% bromophenol blue in 0.5 M Tris, pH 6.8, and then heated for 3 min at 95 °C and subjected to SDS-PAGE in PROTEAN II-type tanks

(Biorad) using the discontinuous buffer system of Laemmli (1970). An optimal acrylamide concentration of 12.5% was selected for the gel. A discontinuous buffer system under electric feed monitored by a Biorad generator (Power-Pac 3000, software version 3.27) was used. Power was constant (17 W), maximum voltage never exceeded 400 V, and the ammeter was set at 100 mA. The gels were stained with Coomassie brilliant blue R-250 O'Farrell.

Determination of molecular mass. The molecular mass of the different proteins was estimated from known standards (Biorad). The method chosen corresponded to a degree 3 polynomial regression model designed from Molecular Analyst software. This model was efficient in describing protein migration in a gel of constant concentration.

Blotting

Electrophoretic profiles were transferred onto nitrocellulose sheets (0.45 μm pore size, Biorad) with a semidry system (Trans-Blot SD Biorad) using Tris buffer (pH 9.2, 48 mmol Tris, 39 mmol glycine, 1.3 mmol SDS, 20% methanol). The nitrocellulose was rinsed out for 5 min in Tris-buffered saline (TBS, pH 7.5) and then blocked for 30 min in TBS-3% gelatine (w:v). Further rinsing with TBS and Tween 20 (TTBS) at 0.05% was necessary, and the nitrocellulose was subjected overnight to the action of rabbit serum at the appropriate dilution (1:2,000) in TTBS at 1% gelatine (w:v). Two additional rinsing in TTBS and one in TBS were necessary to remove unbound antibodies before the marked antiglobulin was labeled with alkaline phosphatase. The blot was then incubated with anti-rabbit IgG antibodies previously conjugated with alkaline phosphatase at a 1:3,000 dilution (v:v) in TTBS-1% gelatine (w:v) and maintained for 30 min in the previous solution. The nitrocellulose was steeped twice in TTBS (5 min) and once in TBS (5 min) and then soaked in Biorad buffer containing nitroblue tetrazolium and 5-bromo-4-chloro-3-indolyl phosphate. The sheet was finally steeped for 10 min in distilled water. All these steps were carried out at room temperature on an orbital shaker.

Antibody Preparation

Two "primary polyclonal" sera were prepared: one antilarval serum (LPm) and one antiadult serum, (Apm). Rabbit antisera were directed against *P. maximus* extracts. Each serum was prepared using two immunized rabbits. Five immunizations per animal were performed by the subcutaneous route in the back of the rabbit. Each 1-mL dose consisted of one volume of protein solution (900 μg of protein antigens in 500 μL of extract) plus one volume of Freund adjuvant. The first immunization was enhanced by complete adjuvant and the following ones by incomplete adjuvant. The second immunization was performed 2 weeks after the first, and the last three at 1-week intervals. The final serum was collected 5 days after the last injection.

Antibody Purification

The entire antiscallop larval serum (LPm) was consumed in 1 day under stirring at 4 °C against an extract of adult *C. gigas*. The purified serum or $LPm_{consumed}$ obtained in supernatant after 45-min centrifugation of LPm-*C. gigas* extract at 4,000 × *g* at 4 °C. Compared to the dilution ratio used for blotting, $LPm_{consumed}$ was less diluted (1:400).

Larval Recognition by Antibodies

All organisms contained in plankton samples were washed twice for 5 min in PBS under soft stirring, incubated for 1 h with 1% glutaraldehyde in PBS, washed twice for 5 min in PBS, incubated 2 to 15 min in 0.2% Triton X-100 in PBS, and washed again for 5 min with PBS. To reduce nonspecific staining, organisms were incubated for 30 min with 3% hydrolyzed gelatine in PBS (w:v). After two washes in PBS (5 min), larvae were incubated overnight in $LPm_{consumed}$ (diluted 1:400 in PBS), rinsed twice with PBS and incubated for 30 min with goat antirabbit IgG labeled: (1) with alkaline phosphatase (Biorad); or (2) fluorescein-isothiocyanate (Interterchim); or (3) with magnetic beads (Dynabeads M 280-Dynal®, 2.8 μm diameter). Once washed with PBS, all organisms were ready for observation, except those tagged with alkaline phosphatase (this stain required a substrate to induce blue color; i.e., nitroblue tetrazolium and 5-bromo-4-chloro-3-indolyl phosphate in Tris buffer, pH 9.0).

All organisms were observed with a universal epifluorescent microscope (Zeiss Orthoplan model) using a 200-W mercury lamp with an appropriate FITC filter. Photos of plankton samples were taken with a mix of transmitted and epifluorescent light. The mercury lamp was turned off to observe the two nonfluorescent-stained samples.

RESULTS

Protein Titration

The protein-dye binding assay kit (Bradford 1976, Lowry et al. 1951) was used to evaluate extraction yield. The concentrations in larval protein measured in *P. maximus* from Argenton and Tinduff were 5 and 1 mg/mL^{-1} respectively; whereas, in Ostreidae, they accounted for 1 mg/mL^{-1} in *C. gigas* and 0.4 mg/mL^{-1} in *O. edulis*. The level in *T. decussatus* was 1.7 mg/mL^{-1}.

Results were similar, regardless of the extraction method used (ultrasound or the French press), but the French press protocol was shorter and, thus, time-saving.

Electrophoresis

After protein determination, the different extracts (larvae and adults from *P. maximus* and *C. gigas*; larvae from *O. edulis* and *T. decussatus*) were subjected to 12.5% SDS-PAGE with Coomassie brilliant blue staining. Adult extracts displayed several bands with similarities indicative of a common profile for the tissues of these two species (*P. maximus* and *C. gigas*). However, the sequence and thickness of the different bands depended on each species and were characteristic of them. Although common strips were found between larval and adult extracts, there were some significant differences within a given species.

Comparative analysis of electrophoretic profiles from the whole set of extracts highlighted several bands, each characteristic of a single bivalve species. The 87 kilodalton (kDa) band corresponded to adult *P. maximus* the 30 kDa one to *P. maximus* larvae, and the 70 and 32 kDa bands, respectively, to *Ostreidae* and *T. decussatus*. However, the protein bands, though specific, were not necessarily immunogenic.

Blotting

Rabbit antibodies on blots, which corresponded to all the electrophoretic profiles after transfer, revealed the immunological response. Serum LPm (Fig. 2A) and APm (Fig. 2B) were applied, respectively, onto the blot at a dilution of 1:2,000.

After full immunization, rabbit antibodies were able to recognize numerous protein antigens. LPm, like APm (both produced

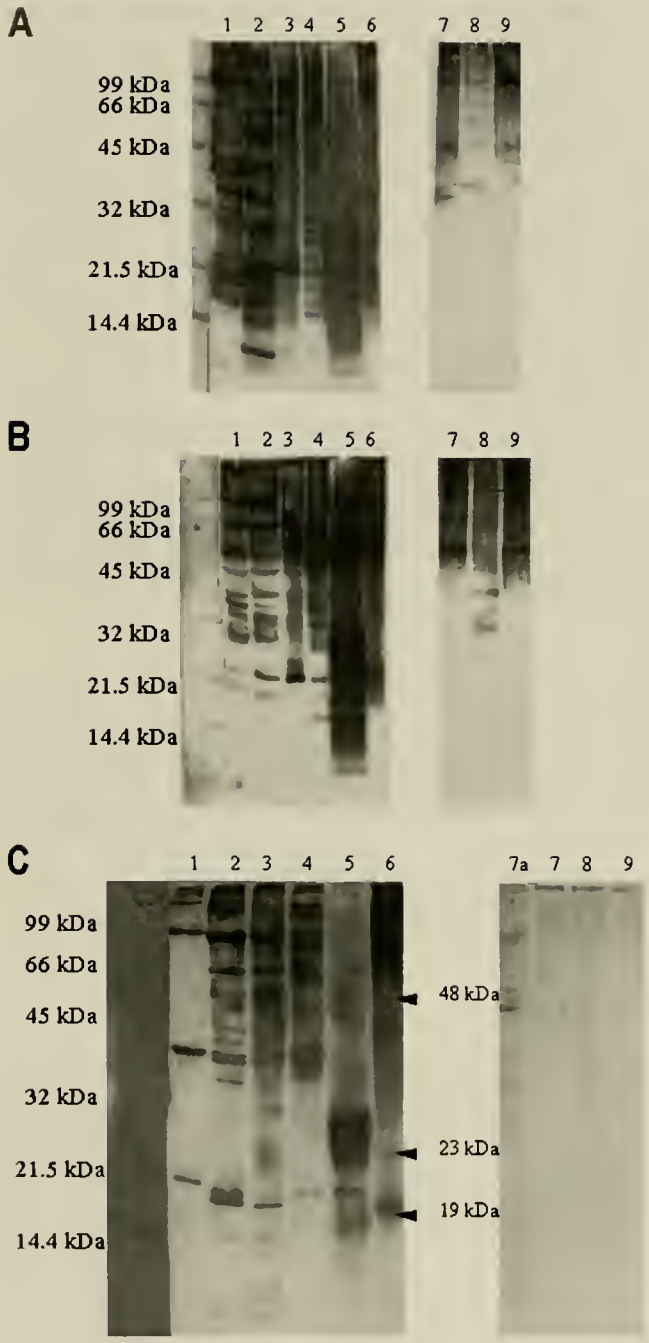

Figure 2. Western blotting of proteins obtained from *P. maximus*, *C. gigas*, *R. decussatus*, *O. edulis*. (A) revealed by APm. (B) revealed by LPm. (C) revealed by LPm consumed. Lanes : 1 to 6 extracts of P. maximus. 1, Adult muscle; 2, Adult mantle; 3, Adult gill; 4, Adult gonad; 5, Adult digestive gland; 6, Larvae. 7a, Adult *C. gigas*; 7, Larvae *C. gigas*; 8, Larvae *R. decussatus*; 9, Larvae *O. edulis*.Molecular weight is indicated as kilo-Dalton for each lane.

from *P. maximus* extracts), reacted with the other bivalve species investigated. Polyclonal rabbit sera allowed us to detect antigenic proteins in scallop extracts by immunoblotting and also highlighted several antigenic bands shared in common by scallops on extracts from other species. Each electrophoretic profile was compared with the two immunoblots, allowing identification of the antigenic bands on the electrophoretic profile and especially detection of those found only in the extract from the chosen species; that is, *P. maximus* larvae.

Immunostaining intensity was correlated with antiserum sensitivity; whereas, Coomassie blue staining was related to protein abundance.

Immunological Recognition of *P. maximus* Extracts

Investigation of the immunological recognition of *P. maximus* extracts showed that LPm serum reacted more specifically with extracts from *P. maximus* larvae than with those from adults; whereas, the reaction with APm was stronger against adults than larvae. The effect of two antilarva and antiadult sera on an adult extract of scallops differed significantly, especially for antigens below 21.5 kDa. This molecular mass constituted a limit below which homology was no longer apparent. For each blot, homologous reaction was always greater than heterologous reaction.

Immunological Recognition of all Other Bivalve Extracts

The antiadult serum (Apm) reacted preferably with *C. gigas* adults The response against larval extracts was evenly distributed along the strips, but did not allow clear identification of the different bands, except for the 100-kDa band, which occurred in all bivalve extracts. This serum did not distinguish between the different extracts. For each of the four extracts; that is, *C. gigas* larvae and adults, *O. edulis* larvae and *T. decussatus* larvae, the antilarval serum (LPm) did not "react" below 16 kDa. Once again, the resulting immunoblotting profiles were characteristic of the species represented. However, LPm serum recognized bands probably shared by all species investigated. A comparison of profiles with that corresponding to the larval extract from *P. maximus* enabled us to identify two specific bands at 48 and 23 kDa respectively.

For the two sera, analysis of the sequences of all bands constituting each profile indicated that each protein extract was specific and that the sera used to recognize them had a strong affinity for the extract, which had induced their elaboration. However, the polymorphism of these sera was too great to allow their direct use as a recognition marker.

The Use of $LPm_{consumed}$ Serum

Because the antigens were generally common to several species and especially to the extract from adult *C. gigas*, antibodies of LPm antiserum were adsorbed on a mixture of *C. gigas* tissues to remove all the antibodies shared in common by *C. gigas* adults and *P. maximus* larvae. The resulting consumed serum, $LPm_{consumed}$ (Fig. 2C), did not react with the extract of *C. gigas* adults. This procedure allowed the capture of antibodies common to this species of bivalve. Among the larval extracts, only that of *P. maximus* was identified by the adsorbed serum. This purified serum confirmed the presence of specific *P. maximus* larval bands at 48 and 23 kDa and identified a new one at 19 kDa.

In Vivo Labeling Process

Indirect antibody staining was performed on the $LPm_{consumed}$ serum (Fig. 3) using three different types of anti-antibodies labeled with alkaline phosphatase (ALP) (Fig. 3A), FITC (Fig. 3B, D) or magnetic beads (Dynal®)(Fig. 3C).

With the first staining procedure, labeling was especially concentrated around the shell on the mantle edge. The FITC antiglobulin allowed us to localize a scallop veliger from a plankton sample

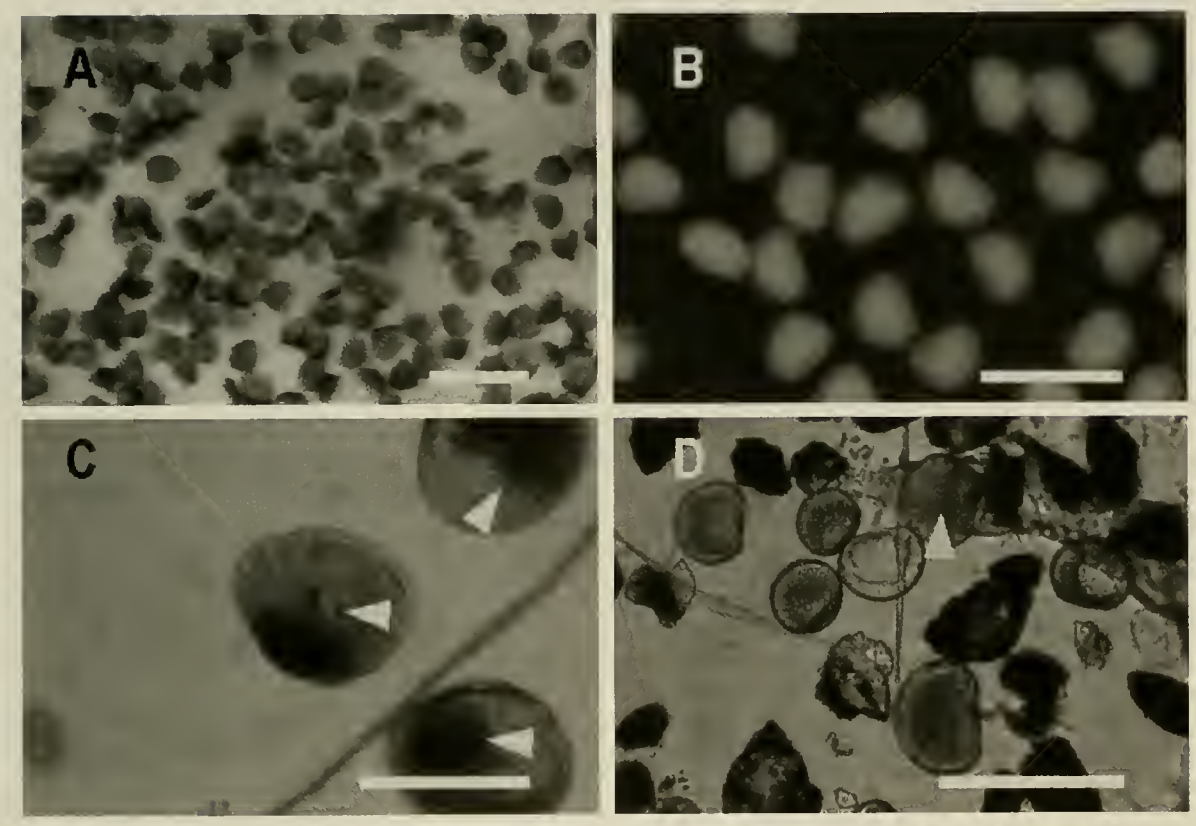

Figure 3. Larval immunostaining. (A) Scallops larvae revealed with Alkaline Phosphatase; (B) Scallops larvae revealed by FITC; (C) Scallops larvae revealed by magnetic beads; (D) FITC labeled scallop larva revealed in a plankton sample. Scale bar = 100 μm.

under epifluorescent microscopy, using mixed fluorescence wavelengths (Fig. 3D) and visible ranges, as suggested by Demers et al. (1993). $LPm_{consumed}$ recognized both D larvae (Fig. 3B) and the pediveliger. The immunomagnetic marker (Dynabeads M-280) formed a complex with $LPm_{consumed}$ to stain scallop larvae, but did not magnetize them sufficiently to allow total collection by magnetic power. Nevertheless, many larvae were captured in the magnetic field (in Fig. 3C, each black point is an aggregate of many magnetic beads).

DISCUSSION

Only monoclonal or polyclonal antibodies can be used to stain bivalve larvae by an immunological technique. The formers have high specificity dependent on selective binding to only one epitope. Demers et al. (1993) tested this technique and found variability in stain intensity within the same batch of larvae. One possible explanation for these results was a differential degradation of antigenic structures attributable to transport and conservation conditions. A second possibility was that antigen expression changed naturally as a result of physical and (mainly) physiological conditions during larval development, as previously reported by Boreham and Ohiagu (1978), Feller (1986), Wang *et al.* (1992), Westin (1972), etc. To decrease the variability in staining intensity, Demers *et al.* (1993) used a pool of monoclonal antibodies selected among three specific lines.

Instead of applying a pool of monoclonal antibodies, we used the rabbit for preparation of a polyclonal serum, which processes several antibodies against all the antigens in a preparation and, unlike monoclonal antibodies, produces stable multivalent interactions conducive to high affinity. Among substances likely to be immunogenic, proteins are most often used, and our extraction procedures sought to obtain a good protein immunogen. Two grinding methods were tested (results not shown). The French press proved not only more efficient for protein extraction from bivalve larvae, but also saved time by avoiding a first extraction with a mixture of water and phenol. In addition, the simplicity and efficiency of this method reduced solvent consumption and larval cost while lowering inhalation risk in a small enclosure. In any event, the electrophoretic profiles were similar with both methods, and analysis identified the bands characteristic of the proteins contained in each extract and thus in each bivalve species.

Extraction yields were always evaluated using the protein-dye-binding assay kit. Protein amounts varied with larvae batches, but were not correlated with the investigated species. Adult extracts presented no difficulties. Regardless of the extraction yields, electrophoretic profiles were characteristic of a single species. When protein levels were below 1 mg/mL^{-1} at the end of extraction for larvae, only the readability of the profile was affected (blurred bands), suggesting a possible correlation between low protein content and blurred profiles. As extractions were always carried out in the same environmental conditions and electrophoresis was performed on the same amount of proteins, the only possible explanation for this yield reduction related to the larvae themselves. In fact, all came from stock farming. Although their shell morphology criteria were fine, their true health conditions remained unknown. Unfortunately, no information was available on the settling capacity of each batch of larvae, which might have allowed the quality of the electrophoretic profile to be related to postlarval settlement (the only true index of larval physiological health).

As noted above, any protein extract from a given bivalve species was liable to produce a polyclonal serum with a specificity sufficient to differentiate one extract from another by immunoblotting. LPm and APm enabled us to distinguish the immunological bands characteristic of a particular *P. maximus* extract, and molecular analysis software allowed us to highlight the succession of bands characteristic of scallops. Extracts from adults and larvae shared several bands. However, this approach neglected the importance of using larval extract as antigens to induce specific "anti-larval" antibodies. Although the specificity of our LPm serum was sufficient to recognize scallop larval extract among several others, it was unable to recognize scallop larvae in plankton (unpublished data).

Two possible procedures were considered to enhance the specificity of our first sera: the capture of specific antibodies by chromatography and the removal of nonspecific antibodies by depletion. The second solution proved easier to implement. To limit potential cross reaction, an attempt was made to purify LPm before subjection to heterologous molecules. The recognized antigen allowed the formation of a complex with antibodies that settled down. After centrifugation, the pellet was easily removed and discarded. Thanks to this technique, a new version of the LPm serum ($LPm_{consumed}$) was obtained, which in immunoblotting tests recognized scallop extracts (mainly from larvae). There were no further cross reactions with larval extracts from other species. The absence of a heterologous reaction allowed us to use this serum for larva labeling. Antibody binding was revealed by three different techniques. First, staining with alkaline phosphatase localized the area of antibody binding near the mantle. Like Demers et al. (1993), we found that no staining disorder was apparent because of shell closure. Alkaline phosphatase was not selective, because it revealed the enzyme bound to the antibody as well as the endogenous enzyme. Revelation of the latter caused background noise in plankton samples (some controls were made on batches of larvae with negative antibodies or with direct incubation in AP substrate), which affected the interpretation of bivalve larval detection. Fortunately, this inconvenience can be avoided if revelation time for the enzyme does not exceed 15 min.

Fluorescent staining gave better results (Fig. 3B, D), allowing scallop larvae to be identified in plankton samples. Because the wavelength used to induce antibody fluorescence sometimes makes phytoplankton fluorescent, some adjustments will be required before a flow cytometer can be used to automate the counting of bivalve larvae. Staining could be improved by replacing the fluorescent marker with another one in order to change the excitation wavelength.

Magnetic beads have already been used in marine biology for isolation of the toxic dinoflagellate *Alexandrium fundyense* from preserved seawater (Aguilera et al. 1996). In our study, beads were found within the larvae. Although their magnetization was too weak for efficient separation of all scallop larvae from plankton, bigger bright-colored magnetic beads could allow the separation and recognition of scallop larva even by an inexperienced researcher. All three of these staining methods allowed rapid identification of bivalve larvae among the whole plankton community.

In conclusion, this first approach to recognition of bivalve larvae indicates the possible benefit of the methods considered here. Electrophoresis revealed immunogenic and specific proteins in several bivalve species. Once purified, such proteins will be able to induce new polyclonal sera endowed with higher capabilities, as recommended by Knudsen (1985) and Diano et al. (1987).

This approach reduces the time required for sorting out and identifying scallop larvae in plankton samples. The use of polyclonal antibodies to stain the larvae extracted from our samples seems promising, and it is likely that this method, after a few adjustments, can be applied in ecological programs or for shellfish farming.

The major interest of this technique is species-specific identification to distinguish close species such as *Pecten maximus*, *Aequipecten opercularis* and *Chlamys varia* in the Bay of Brest, or *Placopecten magellanicus* and *Chlamys islandica* in the Gulf of St. Lawrence in Canada. However, many more families could be treated as well. The use of an immunoassay for identification of marine larval species could save precious time and allow automated identification and measurement of larvae. All these improvements could be useful in shellfish farming to monitor the settlement of postlarvae and determine the best period for setting up a collector.

ACKNOWLEDGMENTS

The authors are grateful to Dr. André-Fontaine and all members of the Laboratory of Infectious Pathology for their comments, suggestions, and technical support. This study was supported by the PNDR (Programme National sur le Déterminisme et du Recrutement).

TECHNICAL PAPERS

Presented at

INTERNATIONAL CONFERENCE ON SHELLFISH RESTORATION

Hilton Head Island, South Carolina

November 18–21, 1998

Journal of Shellfish Research, Vol. 19, No. 1, 334, 2000.

SELECTED PAPERS FROM THE

1998 INTERNATIONAL CONFERENCE ON SHELLFISH RESTORATION:

"FORGING PARTNERSHIPS TO IMPROVE THE HEALTH OF COASTAL ECOSYSTEMS THROUGH SHELLFISH RESTORATION"

Throughout the world there is a growing commitment to the restoration of degraded coastal ecosystems. Political pressure by shareholders in the future of the world's coastal areas has resulted in renewed interest in preserving and enhancing coastal resources at all levels of government. At the local level many volunteer organizations have developed successful programs to identify problem areas, recommend improvements and monitor progress.

The Second International Conference on Shellfish Restoration (ICSR) was held on Hilton Head Island, South Carolina, U.S.A. on November 18–21, 1998. ICSR provides an opportunity for government officials, resource managers, users, and residents to discuss approaches to restore coastal shellfish ecosystems through remediation and pollution abatement, habitat restoration and stock enhancement. Case studies of successful projects are presented, with opportunities for roundtable discussions.

The first ICSR event, held in 1996 was extremely successful. More than 200 participants from ten countries joined together to learn about and discuss innovative management, ecological, and social approaches to restore degraded shellfish habitat and improve coastal ecosystem health. ICSR has been so successful that a European version of ICSR was born—ICSR'99 was organized and held last year in Cork, Ireland.

A unique feature of ICSR is the diversity of individuals who participate. The opportunity for internationally recognized restoration experts to interact with local town planning officials does not occur often enough. ICSR provides that forum and also the building blocks for such interactions to occur in the future.

The papers that follow are representative of the diversity of the topics and individuals that participated in ICSR'98. We are grateful to the many conference sponsors for their support, the members of the ICSR Steering and Program Committees for their time and energy, and to the Journal of Shellfish Research and its editor, Sandy Shumway, for publishing these contributions. We also wish to thank Anne B. Miller for serving as our Technical Editor. Thank you all.

RESTORING THE OYSTER REEF COMMUNITIES IN THE CHESAPEAKE BAY: A COMMENTARY

ROGER MANN
Virginia Institute of Marine Science
College of William and Mary
P. O. Box 1346
Gloucester Point, Virginia 23062

ABSTRACT Restoration of the oyster *Crassostrea virginica* resource to the Chesapeake Bay is a widely supported goal. This manuscript explores the questions of why, how, and in what time frame this should be attempted. Restoration goals based simply on support of a commercial fishery fail to address the role of the oyster as a cornerstone species within the Chesapeake Bay and should only be considered in the context of a long-term sustainable fishery exploitation. The argument is proffered that a restored resource sustaining a fishery at the historical harvest level is unrealistic, because: (1) harvest probably exceeded biological production for much of the recorded history of exploitation; and (2) maximum production, a desired end for fishery support, occurs at approximately half the maximum (virgin, unexploited) biomass, and, thus, can only be achieved with disruption of the virgin complex community structure. Thus, the direct harvest economic value of a fishery based on a restored resource will not reach historical levels if there is an accompanying goal of long-term community development that is self-sustaining in the absence of restoration effort. The role of the oyster as a cornerstone organism and the pivotal link in benthic-pelagic coupling is examined in the context of current and projected watershed management problems, including agricultural and urban development with associated nutrient and sediment erosion issues, in the entire Chesapeake Bay watershed. Restoration efforts to date have focused on rebuilding three-dimensional reef structures, often with subsequent oyster broodstock enhancement, in predominantly small estuaries with retentive circulation to provide demonstration of increased resultant recruitment. Such examples are used to increase public awareness of the success of restoration processes and increase long-term participation in such programs by schools, nonprofit and civic organizations, and commercial and recreational fishing groups.

KEY WORDS: oysters, *Crassostrea virginica*, Chesapeake Bay, reefs, restoration, watershed, management, benthic-pelagic coupling

DEFINING THE PROBLEM, PART I: BIOLOGY, ECONOMICS, PERCEPTION, AND TIME FRAMES

The Chesapeake Bay has a history related to the eastern oyster *Crassostrea virginica*. Much of the biology of the bay over the past 10,000 years is arguably dependent on the reef-forming habit of this cornerstone species. Oysters were an important food source to pre-Colonial native populations, were quickly recognized for their value after Colonial settlement, became the center of a national and international trade before the end of the 19th century, and remained a substantial component of the Middle Atlantic economy through the first six decades of the 20th century. The past four decades have been marked by the appearance and continued destructive effects of two disease vectors, *Haplosporidium nelsoni*, commonly known as MSX, and *Perkinsus marinus*, commonly known as Dermo, in the higher salinity regions of the bay.

When considered together with the cumulative effect of many decades of overfishing and environmental decay, the result is a sadly depleted oyster resource in the Chesapeake Bay. Although consensus is growing that attempted restoration of this resource is a noble and worthwhile cause, the task before us is to ask why, how, and in what time frame this should be attempted.

Given that the oyster has long supported a commercial fishery in the Chesapeake Bay, a logical first question is "Should the revitalization of the oyster fishery be the prime motivation for restoration of the oyster populations in the bay?" Such a question has a number of inherent qualifiers. Fisheries utilize a biological resource to optimize or maximize economic or societal return. Restoration of the resource for this prime purpose would be in a form that optimizes harvest over a defined time frame—a form that may not, as is discussed later, be considered best for optimizing ecological complexity and stability. Economies have time horizons of importance, thus any restoration effort must respect and be responsive to this time frame. The societal component must be equally addressed in that restoration to enhance an economic contribution to a thriving economy must be responsive in a politically expedient time frame; that is, efforts must create a strong public perception of improvement in the face of multiple competing needs for public funding. Economy, perception, and time frame, in addition to biology, become important factors in setting fishery restoration goals.

What might be reasonable goals for a fishery-driven restoration program? The recent and current oyster fishery in the Chesapeake Bay has several components. These must be distinguished from the oyster industry, which includes processing of oysters originating in regions other than the bay. In Maryland, there currently exists an active public fishery prosecuted by watermen who purchase licenses to harvest oysters from resources in regions held in public trust by the State of Maryland. The harvest from this fishery typically exceeds its Virginia counterpart by a very substantial amount. However, this harvest is "underwritten" both by substantial public funds and by the continuing effort by the Maryland Department of Natural Resources to plant shell substrate in selected regions in advance of seasonal oyster settlement (spatfall) and to move the resultant "seed" to regions for optimal growth in the face of potential disease pressure. This program is arguably very responsive to a fishery need; the long-term issue of resource restoration is not a prime mission of the program. A similar program of shell deployment and subsequent "seed" movement on grounds retained in public trust has also been pursued in Virginia. The incremental impacts of disease have reduced the effectiveness of the Virginia program in supporting a continuing industry, and current landings from the fishery are at an all-time low. As in Maryland, the focus of this "plant and move seed" program has been short term, with

no statement on long-term restoration. Virginia also allows leasing of "suboptimal" bottom adjacent to public grounds. These regions sustain a very substantial fishery harvest essentially in grow-out of "seed" oysters but are operated on a put-and-take basis with a 2–3 year growth period. Again, these are strictly for-profit operations by private individuals or corporations with no restoration goal (see Haven et al. 1981a,b). Such efforts have all but disappeared in the past decade as a result of the continued incidence of disease. The losses accompanying the fishery's decline since the major onset of disease have had a subtle societal impact that has generated considerable public debate and, in some instances, sympathy. Commercial fishermen are among the few remaining "hunter-gatherers" in modern society, and their visible demise in the Chesapeake Bay oyster fisheries is viewed (perhaps unrealistically) as a loss of individuals who operate with large amounts of personal freedom in a society that pays little attention to that same personal freedom. A reasonable goal from an economic position would be the restoration of a fishery resource to support a predisease level of harvest, typically several millions of bushels per year for Maryland and Virginia combined, with some enhancement of the societal role supported by the fishery.

Is a fishery-driven restoration to sustain a predisease level of harvest a reasonable goal for ecological restoration? Arguably, no. An examination of the historical fishery harvest finds that the harvest was much greater before to the turn of the century. The combined harvest of oysters in 1865 by Maryland and Virginia alone was approximately 17 million bushels (Hargis and Haven 1988)—enough oysters to bury a football field to the depth of 656 feet! This is an astonishing amount given the primitive dredging and tonging techniques employed, but it illustrates simply the level of fishing pressure employed in the latter half of the 19th century. We know from the works of Ingersoll (1881), Brookes (1891), and others that a century ago strong concerns about overfishing and its eventual impact were expressed to regulatory bodies. Although these concerns stimulated a limited regulatory effort, and the surveys of Winslow in Maryland and Baylor (1894) in Virginia to define the extent of the public resource, the comments did little to abate the revisiting of the "tragedy of the commons." The important issue to this commentary, however, is that the enormous removals of oysters had proportionate impact on the biology of the oyster in the bay. Neither as part of the process of oyster harvesting nor as part of the discussion (minimal for much of the time) on resource management was a formal assessment of stock size or estimate of productivity ever made. However, the fundamental understanding of the importance of these processes was already central to the discussion of marine finfish stocks on both sides of the Atlantic before the turn of the century, as demonstrated by the work of Spencer Baird, G.O. Sars, and their peers. Although very large and obviously old oysters were still abundant in the bay during the heyday (1860s) of harvest (de Broca 1865), we also know from navigation charts prepared by the U.S. Navy before the turn of the century, that three-dimensional oyster reef structures were exposed only at low tide in many regions of the bay. These reefs gradually became permanently subtidal with continued wholesale mining of the resource for both food and industrial (chicken grit to limestone to road surfacing material) purposes. Indeed, gradual submergence of the reefs could not be ascribed to sea level rise!

Proceeding further back in time, we move from the period of highest harvest in the latter half of the 19th century to the period of Colonial settlement, when intertidal oyster reefs were abundant and notable features of the bay. It is this presettlement era that illustrates the most defensible target for restoration goals. Throughout the preceding discussion there has been frequent mention of fishery harvest, but purposely not of biological production. In a well-managed, economically exploited resource, the harvest does not exceed production. Given the lack of assessment and productivity data, a definitive temporal analysis of the post-Colonial settlement harvest in excess of productivity is not possible. However, we do know that the cumulative result has been the removal in less than 400 years of complex reefs that developed over a 10,000-year period, beginning with the inundation of the bay in the current postglacial warming period.

Acceptance of the tenet that cumulative harvest was clearly in excess of cumulative production places the question of restoration for fishery harvest in a new light. The projection of a restored resource being able to sustain a fishery at the historical harvest level is unrealistic because: (1) harvest probably exceeded biological production for much of the recorded history of exploitation; and (1) maximum production, a desired end for fishery support, occurs at approximately half the maximum (virgin unexploited) biomass (as defined in Applegate et al. 1998, Restrepo et al. 1998) and, thus, can only be achieved with disruption of the virgin complex community structure. Indeed, the direct harvest economic value of a fishery based on a restored resource will not reach historical levels unless there is an accompanying goal of long-term community development that is self-sustaining in the absence of restoration effort. It is, therefore, unreasonable to consider a restoration effort for oyster fishery support purposes alone. This conclusion prompts the question, "If the goal is not just the fishery harvest, what end point should restoration goals seek to achieve?" I argue that oyster restoration should be viewed as the reestablishment of (one of several) cornerstones in an ecosystem.

DEFINING THE PROBLEM, PART 2: A CORNERSTONE IN THE ECOSYSTEM

The reason oysters are the focus of shellfish restoration in Chesapeake Bay is their value as a cornerstone species in the bay. Oysters are a major benthic-pelagic coupler; one that supports a diverse food web in higher trophic levels and, as an added bonus, is the basis of a commercial fishery of secondary importance to the food web structure.

How big is the baywide problem? Enormous. The Chesapeake Bay is 298 km long (185 miles), has a surface area of 8,484 km^2 (3277 sq. miles), and has a volume of 71.5×10^9 m^3 (Cronin and Pritchard 1975). Within this context the biology of the oyster deserves attention. Oysters are gregarious and long-lived (therefore, large) in a pristine environment. Spawning efficiency is maximized by simultaneous gamete release in these dense aggregations (see studies by Levitan 1991, Levitan et al. 1991, 1992 for sessile benthic organisms, sea urchins, in spawning and fertilization efficiency). Individual fecundity increases with size (Thompson et al. 1996 using data from Cox and Mann 1992), so dense aggregations of large animals should be a goal of restoration, because they help provide long-term stability through provision of larval forms. Dense aggregations grow in the third dimension (up) in the presence of adequate food. Multigeneration aggregate settlement creates three-dimensional structure as older animals die but remain as substrate for new recruits to the benthos. Three-dimensional structure would, therefore, seem to be a further defensible goal of restorative efforts.

The trophic role of oysters in the Chesapeake Bay and other similar systems has been well studied; therefore, quantitative arguments can be proffered: (1) to support the level of restoration; and (2) to estimate the trophic impact on both nutrient reduction through grazing and higher trophic production through support of enhanced food chains (see Newell 1988, Baird and Ulanowicz 1989, Ulanowicz and Tuttle 1992, for examples). An examination of these contributions underscores the need to consider oyster restoration not as a singular goal but as a component of a holistic approach to watershed management that includes land use practices and the subsequent impact of riverine input to water column processes throughout the bay and its subestuaries. Water column processes are then to be considered in the context of local habitat and benthos (including oyster reefs), progressing to include resident and seasonally migratory transient macrofauna. The complexity and size of the problem has, fortunately, received much attention. The NOAA and EPA Chesapeake Bay Program databases in addition to those of the U.S. Geological Survey (most of these are now available through the World Wide Web) are replete with useful information to guide the restoration plan. To reiterate, a restoration process must be placed in a time context. The changes in the original watershed from forested to a mix of urban, agriculture, and forest occurred over the period from Colonial times to the present; the projected population growth through 2020 within the watershed, especially the coastal regions of Maryland and Virginia, exceeds projected national growth rates. Increases in the human population within the watershed from the current 14 million to 16–18 million are within reason in this time period. Attempts to plan and control growth within the watershed are and will continue to be both politically charged and difficult to resolve. Unfortunately, historical precedent illustrates a general lack of resolve in this country to limit growth and exploitation effectively. Therefore, land use and runoff issues associated with these projections will raise discussion of freshwater diversion, use, re-use, discharge, groundwater use and contamination, and saltwater intrusion. Every item on this list directly affects nutrient and sediment inputs to the bay and will tax the capabilities of recent amelioration strategies to reduce negative effects.

The biological consequences of increased inputs of nutrient and particulate material to the bay watershed are well understood. Nutrients stimulate productivity in excess of the grazing capacity of the resident filter feeders, notably the benthic filter feeders. Sediment loads that inhibit the filtering process exacerbate the situation. With limited grazing, eutrophication is inevitable. Sediment loads similarly inhibit extension of submerged aquatic vegetation (SAV) by limiting light penetration of the water column. The complex nature of the restoration problem is well illustrated by consideration of a two-species interaction: that of oysters with SAV. On a riverwide scale the presence of multiple reef systems with vertical relief in otherwise open bodies of water, like much of the Chesapeake Bay, reduces fetch and, hence, wind-driven resuspension of particulate material in the water column. The presence of fringing reefs reduces sediment input from shoreline erosion. At a smaller scale, filter feeding by oysters reduces water column loads of sediment and plankton; thereby, increasing light penetration and increasing SAV growth. Bottom stabilization by SAV increases water quality; thereby, encouraging a positive feedback loop to oyster growth. There is nonlinearity in this feedback: when the suspended sediment load increases above a certain level, SAV growth essentially ceases, and the response of the oyster filter-feeding rate to sediment load approximates a parabola. Thus, although publicly stated goals of 40% nutrient reduction in nutrient input are laudable, they must be accompanied by a critical reduction in sediment load to allow SAV growth and the oyster–SAV positive feedback interaction to develop. This multifaceted problem of both elevated nutrients and sediments is notable in areas that once supported abundant oyster populations—the James, York, and Rappahannock rivers, and Pocomoke–Tangier Sound—and are given critical status on current Chesapeake Bay Program and EPA World Wide Web sites. Proceeding above a "simple" two-species interaction, Lenihan and Peterson (1998) underscore the sensitivity of the multispecies interaction on reefs to multiple environmental factors.

The enormousness of the potential restoration effort and its primary goal is easily recognized. Is there a logical recovery protocol? I argue, yes. The unique aspects of the biology of the oyster in the bay that must be exploited to facilitate restoration are known: high density and a three-dimensional structure in a location where filter feeding will not be overwhelmed initially by local water quality conditions. In Virginia, these aspects have been used to guide the choice of location for early restoration efforts. A critical issue from both the biological and political view is the choice of sites. Sites must be selected such that the impact of the effort is visible in a short (months to a small number of year) time frame; that is, the signal from the restoration effort must be "visible" above the natural variability or "noise" in the target system. Thus, there is a need to match scale of effort with goals. Attempting wholesale restoration of large river systems at the outset is clearly not viable for either cost or biological considerations, but there are many smaller parts of candidate systems that are attractive. Using such resources as the Baylor ground maps (1894), natural reef "footprints" have been identified that can be cleaned of remaining oysters and used as a base to build three-dimensional structure.

Under the guidance of the Shellfish Replenishment Program at the Virginia Marine Resources Commission, a reef-based restoration effort was initiated in the Piankatank River in 1993 with construction of a single reef at Palace Bar. No broodstock addition was effected at the site. Construction is described in Bartol and Mann (1997). Since its construction, this site has been studied intensively in terms of oyster recruitment and growth (Bartol and Mann 1997, in press, Mann and Wesson unpublished data), disease progression in recruited oysters (Volety et al. 2000, this issue), and development of associated fish and benthic communities (Harding 1999, Harding and Mann 1999, 2000). A contrasting approach was employed in the Great Wicomico River in 1996 (Southworth and Mann 1998). The success of this effort warrants description as a model for restoration programs. The Great Wicomico River is a small, trap-type estuary on the western shore of the Chesapeake Bay that once supported substantial oyster populations. The combined effects of Tropical Storm Agnes in 1972 and subsequent disease mortalities related to *Perkinsus marinus* and *Haplosporidium nelsoni* essentially eliminated these populations. Oyster broodstock enhancement was initiated in June 1996 by the construction of a three-dimensional intertidal reef with oyster shell, followed by "seeding" of the reef in December 1996 with high densities of large oysters from disease-challenged populations in Pocomoke and Tangier Sound. (In these donor locations, the extant oyster population density is too low to effect reasonable probability of fertilization success and subsequent recruitment.) Calculations of estimated fecundity of the resultant reef population suggested that oyster egg production from this source were within an

order of magnitude of total egg production in the Great Wicomico River before Tropical Storm Agnes. Field studies in 1997 indicated spawning by reef oysters from July through September; whereas, plankton tows recorded oyster larval concentrations as high as 37,362 ± 4,380 larvae/m^3 (on June 23)! Such values are orders of magnitude higher than those typically recorded for Virginia subestuaries of Chesapeake Bay in the past three decades and strongly endorse a premise of aggregating large oysters to increase fertilization efficiency. Drifter studies suggest strong local retention of larvae, a suggestion reinforced by marked increases in local oyster spatfall on both shell string collectors and bottom substrate in comparison to years before 1997. Although disease was evident in the population—*Perkinsus* prevalence increased from 32% in June to 100% in July, and intensity increased from June to September—the effort demonstrated that choosing locations where local circulation promotes larval retention combined with reef construction and broodstock enhancement may provide an accelerated method for oyster population restoration. Following the above observation in the Great Wicomico, two reef sites in the Piankatank have been added as part of the broodstock enhancement program using large oysters collected from high salinity regions of the bay where disease pressure remains high. Similar efforts are underway in two small tributaries of the Potomac River (the Coan and Yeocomico), the Elizabeth River, Pungoteague Creek on the bay side of the Eastern Shore of Virginia, and Lynnhaven Bay on the south shore of the Chesapeake Bay mouth. In addition, reefs of various substrate types have been constructed at Fisherman's Island at the southern tip of the Eastern Shore of Virginia and are the site of continuing intense study by Luckenbach and collaborators based at the Virginia Institute of Marine Science Wachapreague Laboratory.

Although there is a clear generic component to these individual efforts of small reefs in small systems, each site is unique along a salinity cline within Virginia waters. They represent a mosaic of habitat types with differing environmental values in both biology and physical structure. Such unique aspects of each reef system are examined further by Breitburg et al. (2000, this volume). Provision of complex physical habitat structure provides opportunity for recruitment by species other than oysters as demonstrated by Breitburg et al. (1995), Breitburg (1999), Harding and Mann (1999, 2000), Nestlerode and Luckenbach (in press), and Coen and Luckenbach (in press). To date, the progression of increasing species richness and complexity in relation to presence or absence of "seeded" oyster broodstock has not been investigated, although it is reasonable to suggest that the presence of the latter accelerates development of the multitrophic community on and around the reefs.

The problem for proponents of reef restoration as a central mechanism to restore oyster resources is not so much the demonstration of biological recruitment in the field as the social and political recruitment of citizens to support such efforts on a long-term basis. Demonstration of "success" in field programs, such as the recruitment event associated with reef construction and broodstock "seeding" in the Great Wicomico River in 1997, provide a vehicle to educate the public and foster vested interest groups. The target audience here is broad, as demonstrated by success to date in developing partnerships, which is illustrated by the following examples. Established environmental nonprofit groups, such as the Chesapeake Bay Foundation, use their considerable resources and infrastructure to support reef efforts on a regional basis. In stark contrast to the "not in my back yard" mentality associated with environmentally adverse programs, reefs are environmentally attractive structures that are desired "in my back yard." Consequently, local citizens groups sponsor reefs in their own "back yards" and school groups grow oysters to seed local reefs as part of the restoration effort. Currently lacking from this team is strong endorsement of both the commercial and recreational fishing communities in the bay. This is surprising, given the obvious long-term advantage to both, but probably reflects the immediacy of benefit that is required to attract these groups. Education is the avenue to forge this relationship, as demonstrated by the active support enjoyed by SAV restoration efforts from the fishing community. An integral part of this education must be the demonstration of the economic value of an ecological asset not just in terms of the commercial and recreational end product. It must be evident that that there is a cumulative positive impact of restored ecosystems in nutrient processing that is preferable to the current "single-payment option" exercised by some point-source nutrient abatement policies. The challenge remains to enjoin a broad citizen base in supporting ecological restoration on a broad base, understanding that they have vested interest as long-term investors in the watershed in which they communally reside with the Chesapeake Bay flora and fauna.

ACKNOWLEDGMENTS

This manuscript was presented as a plenary presentation commentary at the Second International Conference on Shellfish Restoration, convened at Hilton Head, South Carolina, on November 19–21, 1998. This work of the author and collaborators described in this article was supported in part by the EPA Chesapeake Bay Program; the Commonwealth of Virginia, Department of Environmental Quality, Chesapeake Bay and Coastal Programs, and operating funds of the Virginia Institute of Marine Science. Partial support to the author during the period of manuscript preparation was provided by National Science Foundation Grant OCE-9810624. Support to present the manuscript at the Second International Conference on Shellfish Restoration was provided by the National Oceanic and Atmospheric Administration. These sources of support are gratefully acknowledged. I thank my colleagues, James Wesson, Mark L. Luckenbach, Ian Bartol, Juliana Harding, Melissa Southworth, Janet Nestlerode, Francis O'Beirn, and William J. Hargis, Jr., for many interesting discussions on reef biology and the Chesapeake Bay. This contribution is dedicated to William J. Hargis, Jr., who during both his years as director of the Virginia Institute of Marine Science and since retirement has argued tirelessly for oyster restoration in the Chesapeake Bay. Contribution number 2311 from the Virginia Institute of Marine Science.

ABSTRACT The progression of diseases caused by the oyster parasites *Perkinsus marinus* and *Haplosporidium nelsoni* were evaluated by periodic sampling (May 1994–December 1995) of eastern oysters *Crassostrea virginica* on an artificial reef located in the Piankatank River, Virginia. The infections observed were recorded as a function of: (1) prevalence and intensity; (2) oyster size and age; and (3) depth below mean low water at which the host oyster was found on the reef. Only a very small number of oysters were infected with the two species of pathogens on the oyster reef during the first 11 months of life. In the second year of oyster life, epizootiological patterns of disease development followed temperature and salinity trends. Oysters at residence depths ≤45 cm below mean low water exhibited significantly ($P < 0.0001$) lower prevalence and intensity of infections than oysters at depths ≥90 cm. In contrast, oysters at residence depths ≥90 cm had significantly higher growth rates ($P < 0.05$) than those at ≤45 cm. However, size differences were not significant ($P > 0.05$) at the end of the study. Results from this study may be used in managing oyster fisheries on natural or artificial reefs.

KEY WORDS: *Crassostrea virginica, Perkinsus marinus, Haplosporidium nelsoni*, artificial reefs, disease progression, growth

INTRODUCTION

Eastern oysters *Crassostrea virginica* were an economic and ecological resource in the Chesapeake Bay until the early 1900s (Hargis and Haven 1999). Years of overharvesting, diseases caused by the pathogens *Perkinsus marinus* and *Haplosporidium nelsoni*, environmental degradation, and poor resource management have led to a dramatic decline in oyster populations in the Chesapeake Bay (Andrews 1988, Haskin and Andrews 1988). Today, Virginia's oyster population is less than 1% of what it was just 35 years ago. (Wesson et al. 1999). Various efforts have been initiated to rejuvenate dwindling local oyster populations. These include spreading of hatchery-reared juvenile oysters on natural oyster beds in estuaries, spreading oyster shell in an attempt to increase hard substrate for settlement of oyster larvae, and construction of artificial reefs. Rejuvenation efforts, such as spreading thin layers of shell over coastal and estuarine bottom for larval attachment have had limited success. This may be due in part to the lack of three-dimensional complexity observed in natural intertidal communities. Little is known about the colonization and ecology of *C. virginica* on intertidal reefs. In addition, the advantages of oyster settlement on constructed reefs are not well understood. Therefore, this study was conducted to determine: (1) whether residence depth influenced the extent or intensity of disease infection; and (2) the size and age at which oysters became infected and the depths that resulted in significant infections. Observations from the present study are of interest to individuals responsible for constructing artificial reefs and individuals who must determine when to harvest oysters to avoid excess losses.

METHODS AND MATERIALS

Perkinsus marinus Infections

Oysters were assayed for the presence of *P. marinus* using the Ray's fluid thioglycollate medium technique (Ray 1954). Samples of gill and digestive gland were incubated in the medium. Perkins (unpublished data) determined that these organs can more frequently detect the presence of the parasite when infections are very light or light than when mantle or rectal samples are used. The

*Current address: Florida Gulf Coast University, 10501 FGCU Blvd. South, Fort Myers, FL 33965; email: avolety@fgcu.edu

intensity of infections was recorded using a modification of the Mackin scale (Mackin 1962) in which 0 = no infection, 1 = very light, 2 = light, 3 = light–moderate, 4 = moderate, 5 = moderate–heavy, and 6 = heavy.

Haplosporidium nelsoni Infections

Haplosporidium nelsoni was detected using histological, paraffin-embedded sections stained in hematoxylin and eosin. The scale of Burreson et al. (1988) was employed to record intensities of infections where 0 = no infection, 1 = cells were rare, 2 = fewer than two cells per field of view (40× objective), 3 = two–five cells per field of view, and 4 = more than five cells per field of view.

Oyster Sampling

From May 5, 1994 to December 14, 1995, the progression of diseases caused by the oyster parasites *P. marinus* and *H. nelsoni* were evaluated by periodic sampling of oysters that had naturally set on the artificial reef located in the Piankatank River, Virginia, in August 1993. The reef was constructed by the Virginia Marine Resource Commission using aged oyster shells. Details of reef construction are described elsewhere (Bartol and Mann 1997). Sampling of oysters was conducted once every 2 to 4 weeks during the study period. Oysters were obtained by hand or by using oyster tongs, depending on the depth. Six samples of 25 oysters each were obtained for each sample time at two locations on the reef. The base of the reef was 2–3 m below mean low water. Prevalence and intensity (weighted prevalence) of *P. marinus*, and *H. nelsoni* infections, oyster size and age, and depth below mean low water at which the host oyster was found on the reef were measured. The total number of reef oysters sampled was 3,908. With respect to depth, the data were analyzed according to the oyster's residence depth on the reef: ≤45 cm and ≥90 cm mean low water. The observations are expressed in terms of number of weeks after setting. Most of the set in 1993 occurred from August 5 to August 12. To facilitate the handling of the data, August 12 was selected as the date of set.

The progression of infections in the reef-set oysters were compared with the progression through a population of adult oysters. Uninfected, adult oysters (350) were obtained from the upper James River seed beds (Horsehead rock), a region known to have low *P. marinus* and *H. nelsoni* infections in oysters (Burreson and Ragone-Calvo 1996). These adult oysters were placed in plastic mesh bags and then were placed on the Piankatank River reef near the sample sites for the reef oysters; placement was June 16, 1994, the time of the third sampling of the reef oysters. The depth of placement was about midway between the top and bottom of the reef (ca. 100 cm below mean low water). At the time of placement, a sample of 25 oysters was analyzed for the presence of the two parasites, using techniques described previously. To confirm that the parasite detection methodology was being properly applied and to check for patchiness in distribution of the parasites, 350 James River oysters from the same population used on the Piankatank River reef were placed in plastic mesh bags in the York River behind the Virginia Institute of Marine Science (VIMS), an area in which both diseases are commonly present at high levels. Treatment of the 350 oysters held at VIMS was the same as described for the 350 adult oysters deployed in the Piankatank River. Each batch of 350 oysters was sampled (25 oysters per sampling time) simultaneously with the reef oysters until none remained. In the following spring (April 14, 1995), another 350 oysters from the same James River site were placed on the reef and 350 at VIMS as in the previous year and sampled until none remained.

Statistical Analyses

The effects of depth and sampling time (age) of oyster on disease susceptibility (prevalence and intensity of infection) to *P. marinus* and *H. nelsoni* were examined using logistic regression analysis (Agresti 1990). The differences in growth of oysters sampled at ≤45 cm and ≥90 cm depths during different sampling times was assessed using a two-way analysis of variance (ANOVA)

RESULTS

Temperature and Salinity

Temperatures and salinities during the study period showed typical seasonal patterns, higher temperatures during summer months and lower during winter months (Fig. 1). Salinity remained fairly constant during the study period. Temperature and salinity ranges during the study period were 2–30 °C and 10–20 ppt. The conversion between oyster age and sampling dates is presented in Table 1.

Perkinsus marinus Infections

No *P. marinus* or *H. nelsoni* cells were found in the 25 adult oysters sampled before the deployment of the oysters at Piankatank River and VIMS. *P. marinus* prevalence (Fig. 2a) and intensity (Fig. 2b) in oysters set on the Piankatank reef indicate that infections did not appear until 14 weeks into the study when the oysters were 1 year old (Table 1). For the next 44 weeks or until the oysters became 1 year and 10 months old, the number of infected oysters ranged between 15 and 35%; in the ensuing 2 months, the prevalence rose rapidly to 100%. Oysters then exhibited high prevalence (nearly 100%) until the end of the study, when the oysters were almost 2.5 years old. The infection intensities during the plateau phase remained mostly below very light until the end of the plateau (1 year, 10 months old), rose rapidly to moderate to moderate–heavy at 2+ years old, followed by a decline to light and light–moderate at the end of the study.

Perkinsus marinus prevalence was significantly higher ($P <$

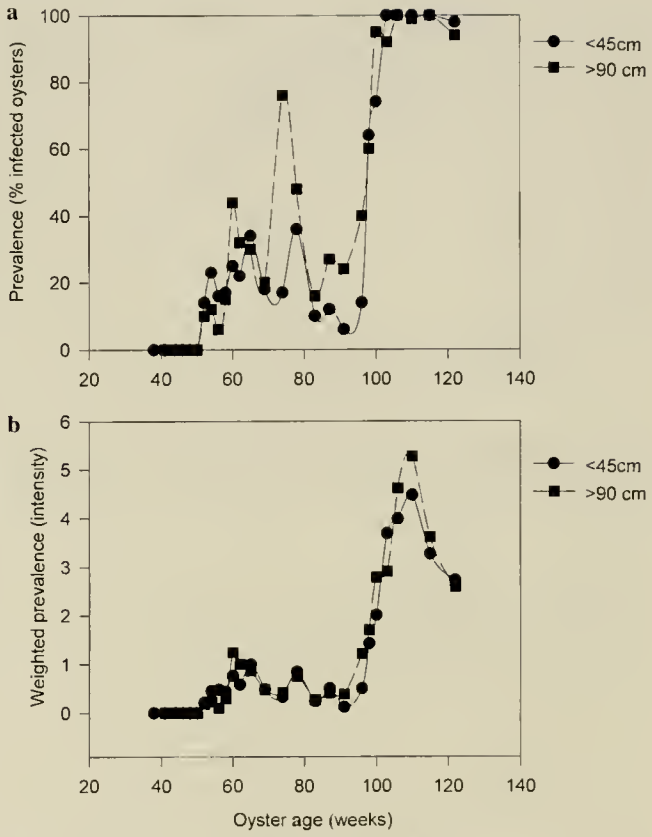

Figure 2. Prevalences (a) and intensities (weighted incidences) (b) of *Perkinsus marinus* infections in Piankatank River reef oysters that set in August 1993 are presented as a function of oyster age and depth of residence below mean low water (≤45 cm and ≥90 cm).

0.0001) in oysters collected from depths ≥90 cm compared to those from ≤45 cm (Fig. 2a). Prevalence significantly increased ($P < 0.0001$) in oysters from all depths with increasing age of oysters, indicating that continued exposure to *P. marinus* or increasing age of oysters results in increased infection. Similar results were observed when *P. marinus* infection was expressed as weighted prevalence. Although the difference in infection intensity was not as great as the prevalence, it was significantly higher at the greater depths ($P < 0.01$) and significantly increased in oysters from both depths with age ($P < 0.0001$).

Perkinsus marinus infection prevalence was the same in adult oysters held in plastic mesh bags at the York River and at the Piankatank River reef during 1994. In 1995, infection was expressed earlier at the Piankatank River and reached 100% 15 weeks before those held in the York River (Fig. 3a,b).

Haplosporidium nelsoni Infections

Prevalence of *H. nelsoni* was markedly different from that of *P. marinus* in reef oysters (Fig. 4a). With the exception of one lightly infected, 50-week-old oyster, the onset of *H. nelsoni* infections did not occur until the oysters were over 1.5 years old, as opposed to the appearance of *P. marinus* in 1-year-old oysters. Thereafter, the infection prevalence of *H. nelsoni* rose rapidly, reaching a maximum of 45% when the oysters were 21 months old. The infections then declined precipitously to almost 0% when the oysters were over 2 years old, followed by a slight increase, which remained below 10% for the final 4 months of the study. The intensities of infections peaked at the age of nearly 2 years, which was 1 month before the prevalence peak was reached, and declined almost as rapidly as did the prevalence (Fig. 4b).

Similar to *P. marinus* infections, oysters collected from ≥90 cm depth had a significantly higher prevalence and intensity of *H. nelsoni* infections compared to those from ≤45 cm depth ($P < 0.0001$) (Fig. 4a,b). In addition, *H. nelsoni* prevalence and intensity increased with increasing oyster age ($P < 0.0001$).

Haplosporidium nelsoni infections (Fig. 5a,b) were nearly nonexistent in the Piankatank River reef oysters during 1994; whereas, in the York River stock, infections were above a prevalence of 60% during the summer and fall of 1994.

Growth and Size

The sampling time and the residence depth of oysters significantly influenced the growth of oysters ($P < 0.001$) (Fig 6). Oysters at both depths grew with increasing age ($P < 0.001$) and sampling time (P 0.001). Oysters at depths ≥90 cm had significantly greater growth than oysters at depths ≤45 cm. Although the differences in size were pronounced during age 56–100 weeks, they were less pronounced during oyster ages 103–122 weeks, and insignificant ($P > 0.05$) at the end of the study. The rate of oyster growth, as estimated from size measurements, decreased 4 weeks

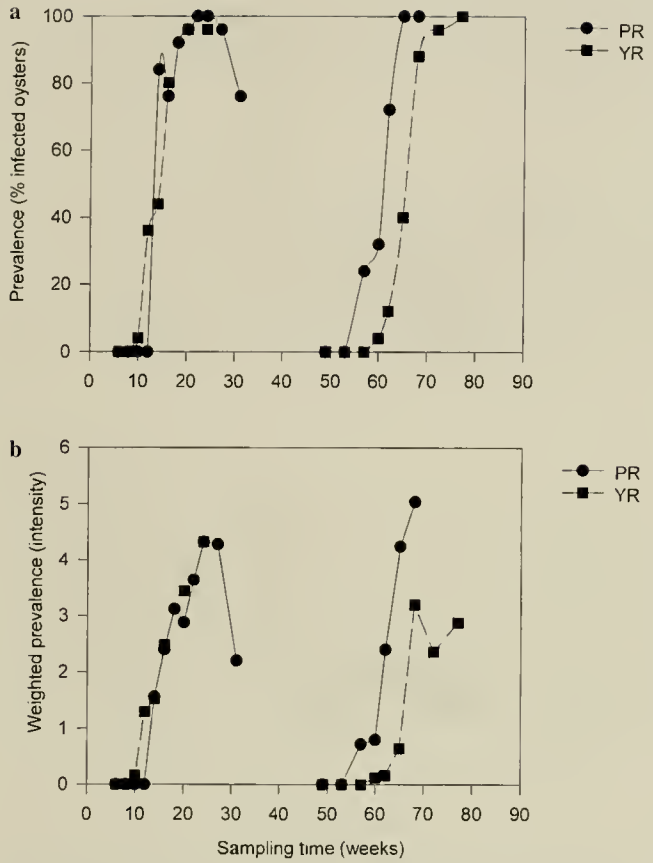

Figure 3. Prevalence (a) and intensity (weighted incidences) (b) of *Perkinsus marinus* for adult oysters imported from the upper James River and placed on the Piankatank River reef and in the York River behind the Virginia Institute of Marine Science. Oysters (350 at each site) were twice placed at the sites and assayed until the populations were depleted by sampling and natural mortalities. The disease organism data are expressed as a function of site and sampling time in the study.

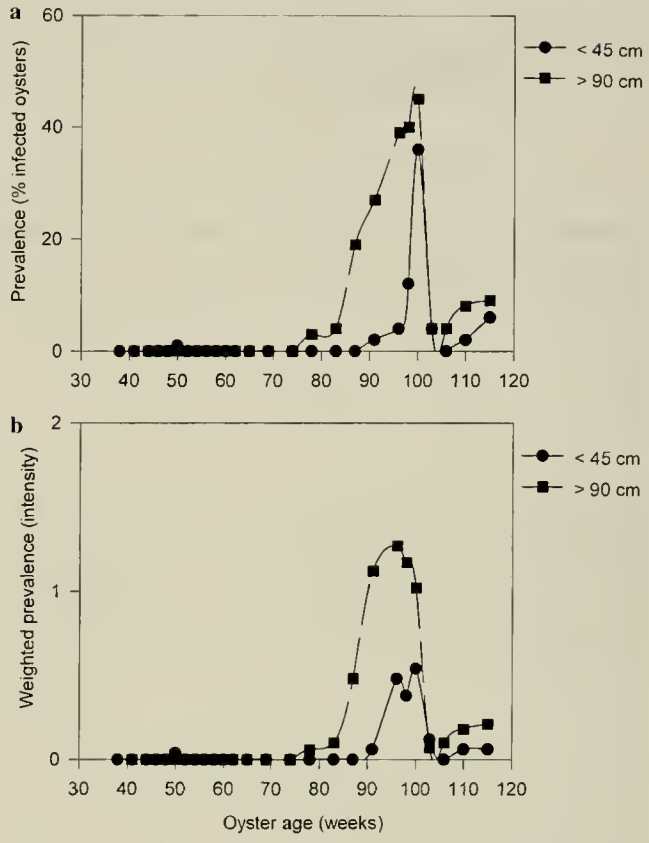

Figure 4. Prevalences (a) and intensities (weighted incidences) (b) of *Haplosporidium nelsoni* infections in Piankatank River reef oysters that set in August 1993 as a function of oyster age and depth of residence below mean low water (≤45 cm and ≥90 cm).

before the first *P. marinus* infections (10 weeks and 14 weeks into the study) (Fig. 6).

DISCUSSION

Interpretation of epizootiological data such as those generated in this study is confounded by many factors that dictate disease prevalence and intensity. These include temperature, salinity, water quality, density of oysters, patterns of water movement, oyster age and/or size, genetic strains, physiological condition, food availability (density and species composition of planktonic food organisms present), and numbers and levels of other parasitic species causing stress on the oysters. A further complication is the fact that the reservoir of *H. nelsoni* infective cells is unknown, and transmission of infections is not from oyster-to-oyster as with *P. marinus*. Despite these complicating factors, patterns of disease progression of both the diseases and oyster growth at different residence depths were apparent. The residence depth of the oysters relative to mean low water is of considerable interest, because the premise behind construction of artificial reefs is that the survival of oysters in the presence of *P. marinus* and *H. nelsoni* will be enhanced if they are grown in the more natural environment of an oyster shell reef off the bottom of the estuary. In fact, this study clearly indicates that residence depth of oysters significantly influences prevalence and intensity of *P. marinus* and *H. nelsoni* infections.

Oysters that are growing at ≤45 cm depth can be expected to have lower prevalences and intensities of infections of both pathogens compared to those living at ≥90 cm depth (Figs. 2a,b. and 4a,b). The prevalence and intensity of *P. marinus* in reef oysters from the current study, while agreeing with those of Mackin (1962), differ from studies by Quick and Mackin (1971) in the Atlantic and Gulf of Mexico coasts of Florida. Weighted incidences (intensities) in their study showed a decrease with increasing depth and no effect of depth on prevalences from intertidal to 3 m below mean low water. Similarly, Burrell et al. (1984) found higher prevalences and intensities of *P. marinus* in intertidal oysters than in subtidal oysters. Mackin (1962) speculated that lower infection prevalences and intensities in intertidal oysters may be because these oysters are not exposed to as many infective cells as subtidal oysters by virtue of the increased amount of time they are closed and not feeding.

Growth of oysters at both the depths (≤45 cm and ≥90 cm) decreased from age 74 weeks, and coincided with increased *P. marinus* incidence in oysters. The decrease in growth of oysters upon acquisition of *P. marinus* infections support the findings of Paynter and Burreson (1991) who observed a decrease in the growth rate of juvenile and adult oysters immediately after or just before infection. *Haplosporidium nelsoni* did not seem for more than 7 months after the change in growth rate, and it is concluded

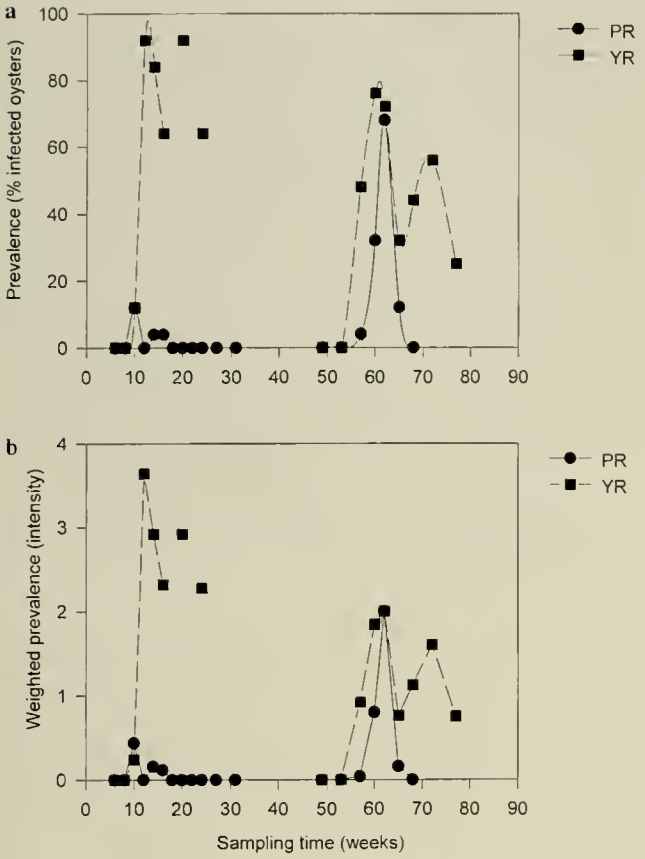

Figure 5. Prevalence (a) and intensity (weighted incidences) (b) of *Haplosporidium nelsoni* for adult oysters imported from the upper James River and placed on the Piankatank River reef and in the York River behind the Virginia Institute of Marine Science. Oysters (350 at each site) were twice placed at the sites and assayed until the populations were depleted by sampling and natural mortalities. The disease organism data are expressed as a function of site and sampling time in the study.

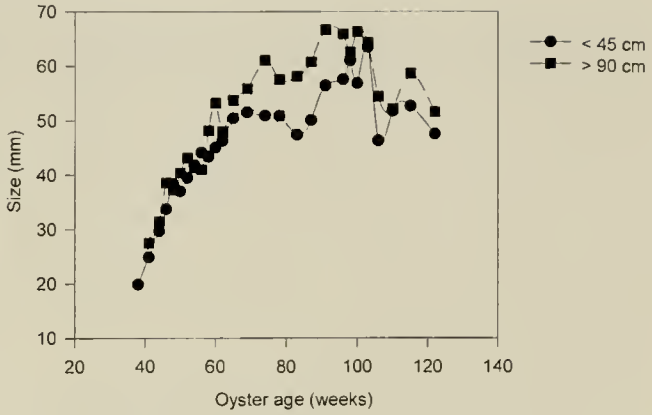

Figure 6. Piankatank River reef oysters that set in August 1993 and were sampled for the disease studies. Sizes are presented as a function of oyster ages and depth of residence below mean low water (≤45 cm and ≥90 cm).

that *P. marinus* was responsible for the decreased growth rate. The decline in oyster sizes after the age of 2 years (65 weeks into the study) is believed to be atributable to death of the larger oysters from infections of the two pathogens.

The higher growth of oysters residing at depths ≥90 cm than those at ≤45 cm is surprising. Given the higher infection prevalence and intensities of both *P. marinus* and *H. nelsoni* in oysters at depths ≥90 cm, we would expect that these oysters would grow less because of disease pressure. The biological, chemical, and physical processes associated with the bottom waters may influence the physiological and defense responses of organisms inhabiting these areas. Organic matter near the bottom of the reef close to the sediment has been speculated (Dahlback and Gunnarsson 1981) to have contributed to the increased growth in oysters from >90 cm. However, at the end of the study, the differences in sizes of oysters from the two depths were not significant.

The present dataset is unique, because it is the first time a population of naturally set oysters of known age has been assayed *in situ* for progression of infections by *P. marinus* and *H. nelsoni* over an extended period of time. Other epizootiological studies have involved placing naturally set or hatchery set oysters of known age in containers in an endemic area or placing adult oysters of unknown ages from nonendemic or marginally endemic areas into containers in an endemic area (Ray 1953, 1954, Mackin 1962, Paynter and Burreson 1991). Placement in containers provides a greater degree of experimental control, but artificial densities of oysters can lead to results different from those in naturally set populations, where distances vary from oyster to oyster.

The prevalence and intensities of infections of *P. marinus* in reef oysters generally followed the patterns dictated by temperature and salinity trends observed in earlier studies (e.g., Soniat 1985, Andrews 1988, Burreson 1991, Burreson and Ragone-Calvo 1996, Ray 1996). *P. marinus* infections in oysters rose in the spring, peaking in October and November, and declined in the winter months into the spring. Intensities of infections were more nearly reflective of previous reports in that the peaks for the two depths were in October and November and the minima in May of the following year (Fig. 2b). Therefore, assuming that temperature and salinity values approximate those of the study period and given the infection intensities and levels, oyster mortalities from *P. marinus* can be expected to begin 13 months after setting, rising most significantly 22 months after setting.

Considering the fact that the salinity values recorded during the first year after setting did not go below 10 ppt, and most of the time were ≥16 ppt, it is reasonable to assume that infections from these two diseases did not occur before May 5, 1994, when sampling began. This assumption is based on other studies that observed when a population becomes infected, the infections do not disappear (or decline) unless the salinity decreases below 10 ppt for an extended period (Andrews and Hewatt 1957, Ragone and Burreson 1993, Burreson and Ragone Calvo 1996).

Previous studies have noted that oysters are refractory to acquiring infections in the first year of life (Ray 1953, 1954) and become increasingly more susceptible into the second year, with significant prevalence, incidence, and mortality being observed then (Andrews and Hewitt 1957). That pattern was observed in the present study (Figs. 2a,b and 4a,b). As mentioned above, the complicating factor was the low level of infection pressure from *H. nelsoni* in the first year of life at the reef. *P. marinus* infections in oysters are dose-dependent (Mackin 1962, Chu and Volety 1997), and small oysters probably filter less volumes of water to acquire enough infective cells of the parasite to initiate an infection (Burreson 1991, Burreson and Ragone Calvo 1996). Results from the current study indicate that in the first 11 months of life, only a very small number of oysters on the oyster reef become infected with

the two species of pathogens. The question that cannot be answered is whether the primary factor in encouraging or permitting a rapid increase in prevalence was temperature, oyster age, or salinity. The best answer probably is that all three played interactive roles.

Data for adult oysters imported from the upper James River seed beds, which represent a disease-susceptible population, confirmed that the two pathogens were present in the study area and in the neighboring area of the lower York River (Figs. 3a,b and 5a,b). They were used primarily to indicate presence or absence of *H. nelsoni*, because it is known to fluctuate greatly, some years being nearly absent from the lower York River region. (Andrews 1988, Haskin and Andrews 1988).

It is interesting to note that *P. marinus* infection prevalence was the same in oysters held in the York River and at the Piankatank River reef during 1994, but in 1995 was expressed earlier in the Piankatank River and prevalence reached 100%, 15 weeks before those held in the York River. One would have expected that the oysters held in the York River would have shown a higher prevalence, because salinities were about 5 ppt above those of the Piankatank River and thus would have presented more favorable salinities for expression of *P. marinus*. On the other hand, in 1994, *H. nelsoni* infections were nearly nonexistent in the Piankatank River reef oysters; whereas, in the York River stock, infections were above a prevalence of 60% during the summer and fall of 1994 (Fig. 5a). These observations reaffirm the necessity of having a stock of susceptible, adult oysters present in a study where juvenile and young oysters are being observed.

The reef oysters ≥2 years old can reasonably be compared to the imported oysters in terms of response to the diseases. Although *P. marinus* prevalences and intensities of infections were similar in the two groups of oysters at the reef, *H. nelsoni* data suggest that the reef-set oysters were more resistant to those infections. Imported oysters at the reef reached a peak of 68% infection (Fig. 5a); whereas, the reef oysters peaked at 36 and 45%, depending upon the depth of residence (Fig. 4a). Likewise, the intensities of *H. nelsoni* infections had a mean level of 2 in imported oysters as opposed to 1.3 in the reef oysters. Therefore, some advantage seems to have been obtained for the reef-set oysters, if we can neglect minor age differences.

The data for *H. nelsoni* was somewhat surprising, because only one oyster was found to be infected in the first year of life (Fig. 4a), and the population did not otherwise begin to show infections until the oysters were over 1.5 years old. It is possible that this lag can be attributed to: (1) the oysters being young and, thus, less susceptible, as has been reported from other studies; and (2) the fact that even the susceptible, imported adult oysters did not acquire very many infections at the Piankatank River reef (Fig. 5a) in the first year of life. It was clear that *H. nelsoni* was present in strength in the nearby York River (Fig. 5a) but not in the reef area, thus illustrating the patchiness in distribution of the reservoir of infective cells, at least in that part of the Chesapeake Bay. The decline in prevalence and intensity of *H. nelsoni* in reef oysters (Fig. 5a,b) was more precipitous that has been previously reported using imported susceptible adult oysters (Haskin and Andrews 1988). In 1995, a different picture of *H. nelsoni* infection distributions in the imported, adult oysters was observed (Figs. 5a,b). The prevalences and intensities were quite similar at the two stations, with the infections appearing earlier at the York River station and lasting longer in the population. Nine more weeks of data were obtained from the York River stock, because the stock at the reef was depleted by mortalities earlier, probably caused by *P. marinus* infections (Fig. 5a,b).

Given the decreased susceptibility of oysters to *P. marinus* and *H. nelsoni* at residence depth of ≤45 cm compared with oysters at ≥90 cm, it seems that piling of shells and constructing artificial reefs is a better strategy for rejuvenating oyster stocks than spreading thin layers of oyster shells on the bottom in estuarine and coastal areas. Future studies should investigate the survival differences in oysters at different depths and the factors responsible for differences in growth rates of oysters at different depths.

ACKNOWLEDGMENTS

This project was funded, in part, by the Virginia Council on the Environment's Coastal Resources Management Program through Grant NA370Z0360-01 (task 16) of the National Oceanic and Atmospheric Administration, Office of Ocean and Coastal Resource Management Act of 1972 as amended. We thank Kenneth Walker and Ian Bartol for assistance in field operations, and Ms Juanita Walker for her technical assistance. Insightful comments on the previous drafts of this manuscript by Dr. William S. Fisher are greatly appreciated. ABSTRACT Prevalence and intensity of *Perkinsus* spp. infections were determined in soft-shell clams *Mya arenaria* during 1990 to 1998 based upon incubation of rectal tissues in Ray's fluid thioglycollate medium. During the study, soft-shell clams were collected from 18 sites in the upper Chesapeake Bay in Maryland. Enlarged hypnospores were found in ~7% (114/1,705) of the soft-shell clams. Peak prevalences occurred in the fall of 1992 with ~53% (16/30) at Piney Point and 50% (15/30) at Eastern Neck, and in August 1995 with ~64% (18/28) and ~37% (11/30) at Cedar Point and Piney Point, respectively. This investigation provides evidence that *Perkinsus* spp. infections in soft-shell clams are more common than previously thought.

KEY WORDS: soft-shell clam, *Perkinsus* spp., Chesapeake Bay, Maryland, infection, intensity

INTRODUCTION

Protozoa of the genus *Perkinsus* have been associated with significant losses of feral and cultured species of bivalve mollusks worldwide. Previous reports of *Perkinsus* sp. infections in soft-shell clams *Mya arenaria* of the Chesapeake Bay have been uncommon (Andrews 1954), and its geographic distribution remains to be determined. Recently, McLaughlin and Faisal (1998a) reported the presence of *Perkinsus* spp. in Maryland soft-shell clams and described the associated histopathological alterations. Most of the infections observed were light in intensity, limited to the gills and palps, and evoked cellular host responses including encapsulation of invading parasites. As infection intensity increased, the parasite was found in nearly all tissues of the soft-shell clam, sometimes causing adverse host effects (McLaughlin and Faisal 1998a, 1999). Interestingly, two species of *Perkinsus* were recently isolated from hemolymph and gills of soft-shell clams collected from the Chesapeake Bay and propagated *in vitro* (McLaughlin and Faisal 1998b). Morphology, life cycle, and molecular characterization studies showed similarities between the soft-shell clam hemolymph isolate and *P. marinus*, and provided evidence that the gill isolate was an undescribed *Perkinsus* sp. (McLaughlin and Faisal 1998a,b, Kotob et al. 1999a,b).

In the assay routinely used for the detection and quantitation of *Perkinsus* spp. cells in bivalves, host tissues are incubated in Ray's fluid thioglycollate medium (RFTM) and enlarged hypnospores then stained with Lugol's iodine (Ray 1952). In soft-shell clams, the use of rectal tissue in thioglycollate assays was found to be effective for diagnosing advanced *Perkinsus* spp. infections (McLaughlin and Faisal 1999). A positive result implies that the infection has progressed from the early encapsulation stage within gill tissues to a more systemic infection spreading into various tissues of the infected clam. In this paper, we report infection prevalences and intensities of *Perkinsus* spp. in *Mya arenaria* collected from 18 sites in the Chesapeake Bay during 1990 to

Prevalence and intensity were based upon incubation of rectal tissues in Ray's fluid thioglycollate medium (Ray 1952).

1998. Prevalences and intensities were determined using rectal tissues in thioglycollate assays.

MATERIALS AND METHODS

Clam Collections

More than 1,700 soft-shell clams were collected in 57 samples (~30 clams/sample) from 18 sites in the Chesapeake Bay (Fig. 1) from 1990 to 1998 by hydraulic escalator dredge. Clams from each sampling site were held on ice and transported immediately to the wet lab facility at the Cooperative Oxford Laboratory (COL), Oxford, Maryland. Clams were held in 76-L glass aquaria supplied with Tred Avon River water or artificial seawater at temperatures between 8 and 20 °C until processed (1–2 days). Salinities were adjusted to approximate those of the collection sites (5–16 ppt).

Ray's Fluid Thioglycollate Assays

Pieces of rectum were excised from each clam and incubated in RFTM (Ray 1952) for 5–7 days. Incubated tissues were subsequently macerated on glass slides, stained with Lugol's iodine, and examined for spherical blue-black bodies characteristic of *Perkinsus* spp. (Ray 1952). Infection intensity was estimated using a semiquantitative scale from 0 (negative) to 7 (extremely heavy infection), modified from Ray (1954) and Mackin (1962). Weighted prevalences were determined by adding the individual assigned intensities and dividing by the number of clams sampled (Mackin 1962).

RESULTS

Perkinsus spp. infections were found in ~7% (114/1,705) of soft-shell clams examined. Infected clams were found at 10 of the 18 sites surveyed (Fig. 1). Temperatures and salinities at sites positive for *Perkinsus* spp. ranged from 2.2 to 25.4 ° C and from 2.2 to 16.3 ppt (Table 1). Peak prevalences of soft-shell clam *Perkinsus* spp. usually occurred in the late summer and fall when salinities and temperatures were highest. A peak in prevalence occurred in the fall of 1992 with ~53% (16/30) at Piney Point and 50% (15/30) at Eastern Neck (Table 1). Prevalence also peaked in August 1995 with ~64% (18/28) and ~37% (11/30) at Cedar Point and Piney Point, respectively. As shown in Table 2, intensities of infections in the rectal tissues ranged from extremely light (stage 1) to heavy (stage 5). Extreme cases (stages 6 and 7) were observed in less than 1% (9/1705) of the soft-shell clams examined. The maximum weighted prevalences observed were 1.17 at Piney Point in September 1992 and 1.57 at Cedar Point in August 1995.

DISCUSSION

Previous reports of *Perkinsus* spp. infections in soft-shell clams are rare. In Virginia, *Perkinsus* sp. was reported to occur infrequently in soft-shell clams and the low infection intensities observed were not associated with histopathological lesions or mortalities (Andrews 1954). Similarly, histological examination of over 3,500 soft-shell clams collected from 20 sites in Maryland during 1969 to 1989 revealed only occasional occurrences of *Perkinsus* spp. (Sara V. Otto, Maryland Department of Natural Re-

sources, Oxford, Maryland, pers. comm.). McLaughlin and Faisal (1999) demonstrated that positive thioglycollate assays using rectal tissue denote advanced, generalized infections of *Perkinsus* spp. in soft-shell clams. This observation was verified in histologic preparations. Hence, the findings from our present study suggest that *Perkinsus* spp. infections may be increasing in soft-shell clams of the Chesapeake Bay. Indeed, soft-shell clams have been shown to host more than one species of *Perkinsus*, one closely related to *P. marinus* and the other an undescribed *Perkinsus* sp. (McLaughlin and Faisal 1998a,b; Kotob et al. 1999a,b). The lack of an effective tool for distinguishing between species of *Perkinsus* within a host limits our ability to attribute the increased prevalence to one or both soft-shell clam *Perkinsus* species.

This apparent elevation in *Perkinsus* spp. infections in soft-shell clams of the Chesapeake Bay parallels increased prevalences and range extensions of *P. marinus* infections in the eastern oyster. Increased occurrences of the oyster parasite were attributed to high salinities from successive droughts during the 1980s, concurrent mild winter temperatures, and movement of infected oysters (Burreson and Calvo 1996). Range extensions of *P. marinus* parasites were further hypothesized to be associated with genetic changes in the host or parasite and/or environmental parameters (Ford 1996). Coincidental increases in soft-shell clam *Perkinsus* spp. in the Chesapeake Bay may be attributable to similar factors. For example, the extension of oyster *P. marinus* into all productive oyster grounds in the Chesapeake Bay in the late 1980s and early 1990s (Burreson and Calvo 1996) coincided with the increased occurrence of soft-shell clam *Perkinsus* spp. observed in this study. Indeed, *P. marinus* was first reported in oysters in Swan Point, Chester River, in 1987 (Burreson and Calvo 1996) less than 3 years before *Perkinsus* spp. infections were observed in soft-shell clams from the same site. Similarly, reduced infection levels of *P. marinus* in Chesapeake Bay oysters during 1994 (Burreson and Calvo 1996) were concurrent with reduced soft-shell clam *Perkinsus* spp. prevalences in the same year.

The high prevalences of soft-shell clam *Perkinsus* spp. at some sites in Maryland during 1992 coincided with the lowest recorded catch of soft-shell clams since 1962 (Connie Lewis, Maryland Department of Natural Resources, Annapolis, Maryland, pers. comm.). The continued low harvests of soft-shell clams in the Chesapeake Bay suggest further investigations on impacts of the parasite to *M. arenaria* fisheries are warranted.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the Maryland Department of Natural Resources and the Maryland Department of the Environment for collection of clams. We also thank the histology staff at the Cooperative Oxford Laboratory (COL) for processing of clams. SUMMER MORTALITY OF PACIFIC OYSTERS, *CRASSOSTREA GIGAS* (THUNBERG): INITIAL FINDINGS ON MULTIPLE ENVIRONMENTAL STRESSORS IN PUGET SOUND, WASHINGTON, 1998

DANIEL P. CHENEY, BRIAN F. MACDONALD, AND RALPH A. ELSTON
Pacific Shellfish Institute
Olympia, Washington 98501

ABSTRACT A study was begun in late 1997 in Puget Sound, Washington, and Tomalas Bay, California, to characterize more precisely the summer mortality of the Pacific oyster (*Crassostrea gigas*) in a variety of culture conditions and locations and to describe definitively the relationship of summer mortality to infectious diseases. Water quality and seasonal factors also were identified. A field component investigated the oysters' thermal stress response and assessed induced thermal tolerance as a means to reduce mortalities. In addition, management practices for commercial cultivation were evaluated as measures to reduce the frequency and extent of oyster losses. Our evaluation of the 1998 data from the summer mortality project supports earlier reports on the rate and timing of mortality events. There were differences in the mortality rates among the varieties of oysters tested, with triploid oysters having consistently higher mortality rates than diploid oysters planted in comparable plots. Trends in mortalities were toward higher rates at or immediately after neap tides when dissolved oxygen was lowest and during periods of elevated air and water temperatures. Relative densities of the phytoplankton *Gymnodinium splendens, Ceratium* spp., and *Psuedo-nitzschia* spp. were higher during the late summer; dissolved oxygen concentrations were correspondingly low, and oyster mortalities were high during this same period. It is likely that Pacific oysters at the study sites experienced varying degrees of chronic stress attributable to multiple environmental factors. Evaluations of effects of those stressors and development of oyster health management strategies are continuing.

KEY WORDS: Pacific oyster, *Crassostrea gigas*, disease, mortality, environment

INTRODUCTION

Pacific oyster *Crassostrea gigas* (Thunberg) production on the U.S. West Coast has not experienced the catastrophic losses from disease plaguing the East Coast; however, mass mortalities occur periodically and continue to threaten commercial production. The syndrome known as summer mortality has been known on the Pacific Coast for at least 40 years. Sharp increases in mortality from June to September are the classic example of summer mortality. The magnitude of the losses has been estimated as up to 50% of the harvestable crop in a given summer, but losses are highly variable by specific location and year. Reduction of these high losses is an integral part of a larger Pacific oyster health management program, being carried out by West Coast research organizations and shellfish farmers, to increase production and sales of seed and edible Pacific oysters.

Background

As early as the 1940s, serious losses of Pacific oysters were reported from Japanese culture locations (Koganezawa 1974). Mortalities occurred during the summer months, and at times exceeded 60%. Although various age groups were affected during an episode, the more severe losses occurred in the older and larger oysters. On the west coast of North America, oyster mortalities have been reported since the late 1950s from Washington, California, and British Columbia (Glude 1975). Again, older oysters seemed to be more susceptible, but the timing and degree of loss was variable. The most severe episodes occurred in shallow, nutrient-rich embayments in late summer when seasonal temperatures were highest.

Japanese researchers advanced a theory of metabolic imbalance related to accelerated reproductive maturation (Imai et al. 1965, Tamate et al. 1965). They concluded that oyster mortalities were related to reproductive maturation and environmental conditions present in growing areas before the end of July. The thought was that mass mortalities in Matsushima Bay associated with high temperatures and nutrient-rich waters led to accelerated reproductive development.

In Washington state, a similar metabolic imbalance was proposed, although regional water temperatures are generally lower than those in the Japanese growing areas (Perdue 1983, Perdue et al. 1981). Scholz et al. (1973) believed mortality was associated with gonad resorption. These studies also noted a high variability in mortality rates between growing areas in close proximity.

Studies to produce resistant oysters and genetically altered broodstocks were conducted by the University of Washington in the 1970s and 1980s. Selective breeding experiments showed that survival could be increased significantly, but it was accompanied by a severe decline in production yields (Beattie 1984). Surviving oysters were smaller, slower growing, and thinner than susceptible oysters and had little commercial use. The subsequent development of triploid Pacific oysters, which have poorly developed gonads, offered a promising option to reduction of summer kills (Allen et al. 1989).

The role of infectious agents in summer mortalities of Pacific oysters and other *Crassostrea* species has been studied extensively in Asia, the United States, and Europe (Sindermann 1990, Elston 1993). Early studies by Japanese investigators discounted the role of a bacterial disease now known as nocardiosis, because a correlation with infection and mortality could not be established (Numachi and Oizumi 1965). However, nocardiosis has recently been associated with some episodes of summer kill (Elston et al. 1987, Friedman 1990, Friedman et al. 1991). A herpes-like virus infection has been seen in larvae and seed oysters of Pacific oyster from hatcheries on the Atlantic coast of France (Nicolas et al. 1992, Renault et al. 1994, Renault IFREMER, pers. comm. 1997). These authors reported summer mortalities of 80–90% in infected seed. Similar herpes-like infections have not been observed in U.S. West Coast Pacific oysters.

PURPOSE AND OBJECTIVES

In late 1997, the Sea Grant Oyster Disease Research Program funded a multiyear study to further investigate summer mortality in Pacific oysters. This project was designed to test hypotheses relating to mortalities of Pacific oysters on the U.S. West Coast and to recommend measures to reduce those mortalities. The specific objectives were the following.

1. Perform studies that will provide health and disease information for Pacific oysters in areas experiencing high frequencies of summer mortality.
2. Carry out a comprehensive survey of environmental conditions occurring in the affected areas.
3. Evaluate in field trials the influences of environmental factors on stress proteins, morbidity, and mortality of diploid and triploid Pacific oysters, under a variety of culture conditions.
4. Identify and test short-term mortality reduction options for shellfish farmers and resource managers; and make recommendations for longer term study.
5. Compile information on Pacific oyster mortality from shellfish farmers and researchers on the U.S. and Canadian West Coast.

This report describes the first-year activities and findings of that study. Project activities reviewed in this report include:

1. experimental design and setup of study sites and treatment groups in Puget Sound, Washington;
2. monitoring of mortality, condition indices, growth, and associated fauna and flora; and
3. monitoring of water quality parameters and phytoplankton.

Related activities during the same period, not reported here included:

1. compiling information on summer mortality events from Tomales Bay, California, and other locations; and
2. sampling for stress protein, conducting histopathology analyses, and assessing pathology associated with mortality.

METHODS AND MATERIALS

Site Selection

The original project design called for field sampling and screening stations in two locations in south Puget Sound (Mud Bay and Totten Inlet) and one in north Puget Sound (Sequim Bay). The Mud Bay and Sequim Bay sites were believed to have a high incidence of summer mortality; whereas, the Totten Inlet site was selected as a low mortality control. Each site was dedicated for the duration of the project on private oyster grounds owned by Taylor Shellfish Farms and the Jamestown S'Klallam Tribe.

Preliminary siting meetings were held with shellfish farmers and researchers in February 1998. As a result of these meetings, the decision was made that the project would benefit from two additional Puget Sound sites. One site was to be near the community of Allyn, in North Bay, south Puget Sound. This site was being intensively monitored for toxic phytoplankton and other marine algae, had experienced consistent annual mortalities and, in 1997, had very high levels of both *Vibrio parahaemolyticus* and paralytic shellfish toxicity (PSP). The second site was in Eld Inlet and located to continue observations on Pacific oysters imported in 1994 from Tasmania. During a 1997 to 1998 study, these oysters were found to have both lower mortality and higher growth rates than a comparable population of native Pacific oysters (Kittel 1998). Finally, late in the summer of 1998, a sixth site was added in Tomales Bay, California. Sampling of this site was directed at an histopathological analysis of seed mortality during the September to October period. No environmental or water quality data were gathered. The locations of each of the five Puget Sound sites are shown in Figure 1.

Site Design and Setup

The experimental design called for a combination of shellfish health, environmental, and general biological monitoring at each study site. In conjunction with pathogen screening, we monitored water quality, stress proteins, oyster size, condition, mortalities, associated fauna and flora, and other relevant features. Experiments were designed to challenge, under commercial conditions, seed, yearling, and market-ready oysters held on the bottom and in culture bags placed on the bottom and on racks. All plots were located in or immediately adjacent to commercial grounds.

All experimental sites in Puget Sound were established between mid-April and late May 1998. Approximate bottom elevations mean lower low water (MLLW) were: Sequim Bay 0.0 m (0 ft), Totten Inlet 0.9 m (3 ft), Mud Bay 0.3 m (1 ft), Allyn 0.3 m (1 ft), and Eld Inlet 0.0 m (0 ft). Nearly 26,000 diploid and triploid oysters of varying sizes were transplanted from existing farm beds and nursery facilities. An additional 2,000 oysters were stockpiled to provide replacement animals and specimens for histopathology and stress protein sampling. The make-up and density of oysters in the culture treatments at each site are shown in Table 1.

Instrumentation was also deployed for continuous or repeated

[1] Cultched seed: 2–15 mm diameter seed attached to shell, 4–8 seed per shell; single seed: 15–30-mm-diameter singles; yearling: 1–2 years old and 80–100 mm-long singles; market ready: 2–3 years old 100–150-mm long singles or in clusters. These oysters were spread evenly on the bottom or placed in 1.0 × 0.5 = m 10-mm plastic-mesh growout bags.

monitoring of key water quality parameters. Onset© miniature data loggers were placed in waterproof cases and installed on the bottom at each study site to sample ambient water and air temperatures. We also assembled and deployed similar Onset© data loggers fitted with dissolved oxygen (DO) probes and operational amplifiers for long-term, continuous monitoring of DO.

Site Surveys and Monitoring

Field Sampling and Mortality Monitoring

Size data and condition indices were collected for each group of animals during the setup phase of the project. Since setup, up to 11 sampling sessions have been performed at each of the five Puget Sound sites. Monitoring of the test sites began before the anticipated onset of the summer mortality events in late June and continued during each low tide cycle, approximately every 7 to 14 days. Moribund oysters and outright mortalities within each of the test plots were recorded, flagged, and documented photographically during each survey. Mortalities were counted when there was obvious shell gape, and the animals lacked any closure response. Oysters considered moribund were gaping but were able to produce a closure response.

Moribund animals were removed and preserved for histological inspection. Live specimens were collected routinely for use in the histopathology and stress protein portions of this study. The original densities of the test plots were maintained by replacing animals removed from the plots with others stockpiled in nearby plots, planted at similar densities.

Environmental Monitoring

Intertidal water and air temperatures were recorded continuously, a reading was taken every 24 to 30 min at each site beginning in mid-May 1998. Continuous DO data (readings every 15 to 30 min) were also obtained at the Mud Bay site in Eld Inlet, beginning July 11, 1998. YSI© oxygen–temperature–salinity and pH meters were used to measure these water quality parameters during selected flood and ebb tides. A water sampler bottle was

used to collect water samples at depth. Meteorological data were collected from available weather instrumentation. Tide data were computed with tide prediction software.

Phytoplankton samples were collected by fine-mesh (10-μm mesh), 0.25-m diameter ring nets at the Mud Bay and Allyn sites during each sample period. Living or formalin-fixed net samples were examined using light microscopy to generate a species list and determine species relative abundance (dominant, many, few).

An oyster condition index (CI) was derived from 11 to 31 randomly selected market-size oysters in the May to June 1998 period at the Sequim, Allyn, and Mud Bay sites. A second series of samples were taken in October to November 1998 at the above sites and in Totten Inlet. The CI was used to determine the quality or "fatness" of oysters. All CI calculations employed the gravimetric method discussed in Schumacker et al. (1998).

RESULTS

Shellfish Mortalities

Substantial mortalities of Pacific oysters occurred at the Totten Inlet, Mud Bay, Allyn Bay, and Tomalas Bay sites during the middle to late summer. Mortalities at the Sequim Bay and Eld Inlet sites were negligible.

Cumulative and average daily mortalities at four of the Puget Sound sites are shown in Table 2 for market-ready diploid and triploid oysters. Mortalities for the reported time periods ranged from 40 to 56% for triploid oysters in Totten Inlet, Mud Bay, and Allyn Bay; and 31 to 45% for diploid oysters in Totten Inlet and Mud Bay. Considerable variation was seen in seed oysters, with Totten Inlet experiencing higher die-offs than either Allyn or Sequim bay. We have limited sampling information from the Tasmanian stocks at the Eld Inlet site. Mortalities at this site over a 83-day period were 3.6% for Tasmanian Pacific oysters, 9.6% for a control stock of native Pacific oysters, and 1.4% for Pacific oysters transplanted from Mud Bay. The trend that Kittel (1998) reported seemed to be continuing.

The progression of Pacific oyster mortalities throughout the summer was followed by means of weekly to monthly field observations. Mortalities were calculated as a percentage average daily mortality between each sample period for Sequim Bay, Totten Inlet, Mud Bay, and Allyn datasets (Fig. 2). Sequim Bay did not exceed 0.04% per day at any time, and 7 out of 10 samples were less than or equal to 0.01%. The other sites experienced elevated mortalities beginning in early July in Totten Inlet and early August in Mud Bay and Allyn Bay. Totten Inlet was unusual—very high mortality occurred within the first 4 weeks of onset, mortality declined to a low level after that. Allyn and Mud bays had increasing but variable mortalities beginning later in the summer, mortalities continued at moderate levels through the end of September.

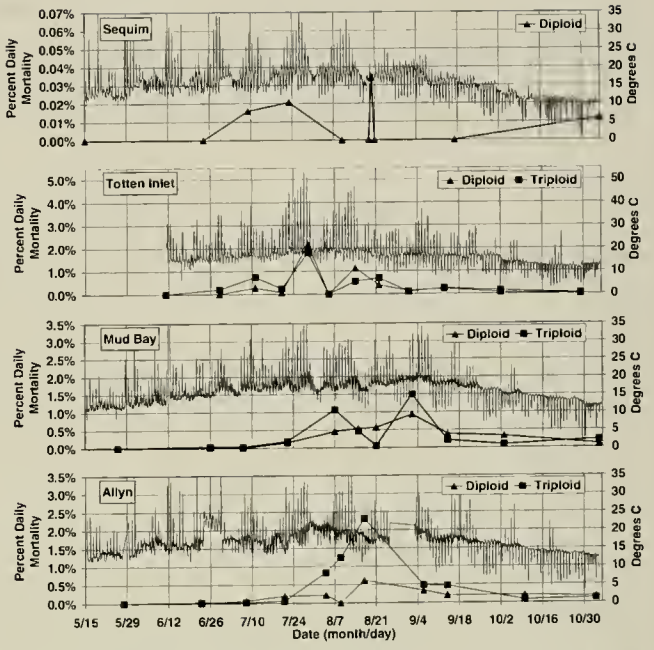

Figure. 2. Percentage daily mortality (left-hand axis) and ambient water and air temperatures (right-hand column) at Puget Sound summer mortality study sites, summer–fall 1998.

Triploid mortalities began earlier in the summer and spiked more rapidly and at a higher rate than the diploid treatments. Daily diploid mortalities did not exceed 0.6%; whereas, the average rate of triploid treatments approached 2.5%. Triploid mortalities in Mud Bay and Allyn Bay were also high; however, they tended to track the diploid die-off closely. Triploid mortalities were most pronounced in Allyn (Fig. 2). The high and sudden mortality in Allyn was unfortunate, because the commercial beds were largely planted as triploids. All triploid oysters in those commercial beds exhibited a rate and timing of mortality onset that was similar to the treatment plots.

Environmental Monitoring

All sites for the summer mortality sampling are in protected estuarine embayments. The Sequim Bay, Allyn Bay, and Mud Bay sites are in shallow heads of inlets strongly influenced by tidal exchange and freshwater input from the surrounding uplands. Water column data for Sequim Bay, Totten Inlet, Mud Bay, and Allyn Bay for the summer to fall 1998 period are shown in Table 3. High pH levels were recorded during the early summer, probably reflecting high primary productivity during this period. Salinities were depressed only for brief periods after heavy rainfall events in Mud Bay and Allyn Bay.

Temperature

Ambient temperatures were monitored at all survey sites during the 1998 sampling period (Fig. 2). Tidal period played a large role in the duration and range of recorded temperatures. Low daytime tides coupled with intense insolation resulted in high ambient air temperatures and elevated water temperatures on the incoming tide. Peak temperatures neared 53 °C (or 127 °F) and frequently

exceeded 40 °C during low-tide exposure in Totten Inlet (Fig. 2). Air temperatures exceeded 25 °C during low tide at all stations between late June and early September.

Dissolved Oxygen

Dissolved oxygen (DO) concentrations recorded above the sediment surface in Mud Bay fluctuated from less than 1 mg/L (ppm) to nearly 12 mg/L. Summertime DO was closely linked with the tidal cycles. A long period of neap tides with low and slack water during the evening resulted in a daily and successive reduction in DO. For example, from September 20 through October 2, the DO was between 0.5 and 2 mg/L for about 9 days (Fig. 3). Similar, but shorter duration, declines in DO were also recorded in middle and latter parts of August. A closer look at the late September extreme low DO event revealed the following: (1) the DO was lowest at slack water; (2) if the meter was exposed (tide below about 0.3 m MLLW) the DO spiked, indicating a measurement in air; and (3) water temperature was very constant and declined only slightly in the early morning. From the second week of October onward, records from Mud Bay showed a gradual increase in DO, with numerous strong peaks (DO above 8 mg/L) corresponding to low-tide exposure to the air and circulation during strong spring tides.

Phytoplankton

Phytoplankton taxa observed in samples taken from Puget Sound summer mortality sites are listed in Table 4. A total of 32 samples were screened from June 23 to December 2, 1998. Samples taken through mid-July were composed primarily of centric and pennate diatoms and *Ceratium* spp. Beginning in mid-July and continuing through early October, *Gymnodinium splendens* and *Ceratium* spp. were typically dominant taxa, followed in relative abundance by *Chaetocreros* spp., *Coscinodiscus* spp., and *Psuedo-nitzschia* spp. Dinoflagellates declined after mid-October, and *Ditylum brightwellii*, *Coscinodiscus* spp., and *Psuedo-nitzschia* spp. were the dominant taxa.

Condition Index

Average condition indices of market-size oysters from summer mortality study sites ranged from 8.78 to 11.08 in spring 1998 (Table 5). The same size group of animals sampled in fall 1998 had

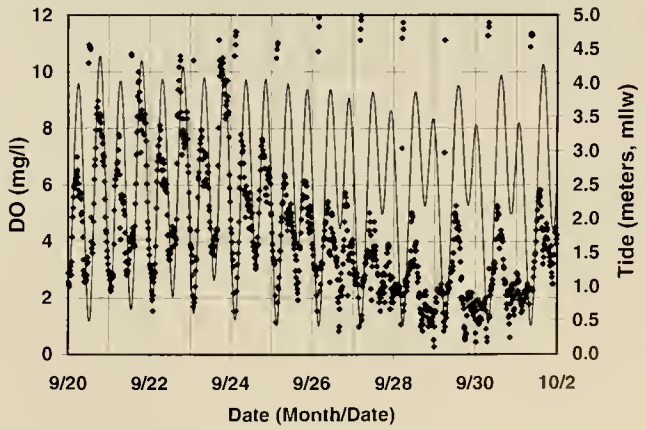

Figure. 3. Tide levels (lines) and dissolved oxygen (dots) 6 cm above the sediment surface at the Mud Bay, Puget Sound, summer mortality study site, September 20 through October 2, 1998.

Alexandrium spp.
Protoperidinium spp.

average indices of 4.78 to 8.78. Triploid and diploid oysters had similar indices in the fall sampling. Allyn had the lowest average index of three sites in the spring, and over-all lowest indices in fall sampling. Many of the Allyn oysters were visibly thin and transparent.

DISCUSSION

The published literature and anecdotal reports suggest many of the mortalities occurring in Pacific oysters are the result of multiple factors or stressors, including pathogens, elevated temperatures, low DO, xenobiotic stress, and the physiological stress associated with reproduction. It is likely that multiple chronic stressors may combine to bring about mortalities and that an oyster's ability to deal with a particular seasonal stress, such as temperature, may be the deciding factor as to whether that organism will survive. Our evaluation of the first year's data from the summer mortality project supports observations reported by Glude (1975) on the rate and timing of mortality events. In addition, there seemed to be significant differences in the mortality rates among the varieties of oysters tested. Triploid oysters at the Mud Bay, Allyn Bay, and Totten Inlet test sites experienced a cumulative mortality rate 8 to 28 percentage points higher than the mortality rates of diploid oysters planted in comparable plots (Table 2). Mortality events trended toward higher rates at or immediately after neap tides when DO was lowest. Extreme air temperature spikes and increasing ambient water temperatures were also occurring at the same time. However, high temperature alone may not be lethal. Many oysters at the Totten Inlet site survived repeated exposure to temperatures over 40 °C (Fig. 2). We have not yet measured the internal temperatures of Pacific oysters in parallel with our temperature readings recorded by our data loggers. Larger oysters with thick shells, positioned vertically and partially embedded in sediment would probably have lower internal temperatures than the external (environmental) temperatures recorded by the data loggers.

A preliminary assessment of phytoplankton occurring in the study sites suggests a possible link between the densities of *Gymnodinium sanguineum*, *Ceratium* spp., *Pseudo-nitzschia* spp., and other dominant taxa with the onset of summer mortality. *G. sanguineum* was abundant in Mud Bay and Allyn Bay, and at times the water in Mud Bay had a pronounced orange-red tint. Dissolved oxygen concentrations were low and mortalities were high during this same period. These observations parallel early accounts of the interactions between oyster mortality and phytoplankton. Nightingale (1936) reported numerous occurrences of "red-tides" associated with *G. sanguineum* (densities ranged from 37 to 15,800 cells/mL). He attributed losses of Olympia oysters *Ostrea lurida* directly or indirectly to those red-tide blooms. Nightingale (1936) also assessed the effects of *G. sanguineum* in aquaria containing Olympia oysters. He used cell densities typically seen in Puget Sound blooms and observed responses ranging from excessive mucus production to shell closure and a cessation of feeding. More recent literature has associated *G. sanguineum* with fish kills and toxicity (Steidinger and Tangen 1996), and Carolyn Friedman (Bodega Marine Laboratory, pers. comm. 1998) reported seed mortalities in Tomales Bay during *G. sanguineum* blooms.

It is likely that oysters at the Puget Sound summer mortality study sites experience varying degrees of chronic stress because of the water quality and biological changes we observed at those locations. Therefore, a critical factor for survival may be the oyster's ability to elicit a satisfactory response to a suite of summer stressors. The Pacific oyster summer mortality project will continue through 2001 to describe the primary stressors affecting oyster survival, assess the effects of specific phytoplankton taxa, evaluate the role of infectious disease, and identify practical methods and tools to increase the predictability and management of mortality events. Future project reports will discuss histopatholog-

ical events leading up to and resulting in oyster mortality, and physiological and biochemical responses of the animals to elevated temperatures and other stressors.

ACKNOWLEDGMENTS

This project is a cooperative industry–research-agency effort. Shellfish industry partners provided culture sites, shellfish product (single seed, cultched seed, and mature oysters), material and supplies, laboratory support, and field staff for site setup. They included Taylor Shellfish, Inc.; Jamestown S'Klallam Tribe; Chelsea Sea Farms; and Hog Island Shellfish Farm. Scientific contributors included: Gary Cherr and Amro Hamdoun at the University of California at Davis, Bodega Marine Laboratory; Rita Horner, University of Washington Department of Oceanography; and Sherwood Hall, U.S. Food and Drug Administration, Office of Seafood. This paper is funded by a grant from the National Oceanic and Atmospheric Administration. The views expressed herein are those of the authors and do not necessarily reflect the views of NOAA or any of its sub-agencies.

ABSTRACT We report here the experimental design and observations from the premanipulation year of an ecosystem-level study investigating the hypothesis that oyster reefs control the structure and function of intertidal creeks. A group of eight tidal creeks in North Inlet, South Carolina, USA, dominated by oysters, *Crassostrea virginica* (Gmelin), were studied using a replicated BACI (Before-After Control-Incident) design in which all creeks are sampled simultaneously. Before the start of the premanipulation year, oyster biomass in the creeks was adjusted to 8 g db/m^2. Detailed geomorphological observations were made on each creek as the study began. Nutrients and chlorophyll *a* were measured weekly in each creek and exhibited seasonal and interannual influences. Intensive planktonic-microbial loop samplings were conducted seasonally and suggested a diatom-dominated winter community controlled by nutrient availability and a microflagellate-dominated summer community controlled by grazing. Nekton biomass exceeded oyster biomass in most creeks during the summer. As expected, oyster growth decreased from summer to winter, and survival was higher in winter. In the study's second, or manipulation year, the role of oysters will be tested by removing them from four creeks.

KEY WORDS: ecosystems, estuarine, oysters, creeks, plankton, nekton, field experiment, microbial loop

INTRODUCTION

Within southeastern Atlantic Coast marsh–estuarine ecosystems, tidal creeks are channels that allow the movement of organisms and materials between the marshes and mud-flats and the deeper portions of the estuary. Intertidal oyster reefs are prominent, intensely heterotrophic components of these creeks. These reefs can make an impact on biodiversity and productivity in marsh–estuarine systems by

1. providing three-dimensional (3-D) structures that increase habitat heterogeneity and supply space to support diverse assemblages of benthic and nektonic organisms (Wells 1961, Dame 1979, Tsuchiya and Nishihira 1986, Zimmerman et al. 1989, Breitburg et al. 1995, Wenner et al. 1996, Breitburg 1999),
2. modifying tidal creek morphology and hydrodynamics by structurally altering creeks, changing tidal flow patterns, and increasing water residence times (Keck et al. 1973, Frey and Basan 1978, Bahr and Lanier 1981, Lenihan et al. 1996),
3. filtering large amounts of particulate material from the water column and releasing large quantities of inorganic and organic nutrients into creek waters (Haven and Morales-Alamo 1970, Newell 1988, Dame et al. 1989, Dame 1993, 1996).

Despite numerous speculations and scaled-up estimates of the influences of filter-feeding reefs on estuaries and creeks (Cloern 1982, Officer et al. 1982, Dame et al. 1986, Newell 1988, Alpine and Cloern 1992, Ulanowicz and Tuttle 1992), no comprehensive *in situ* ecosystem-scale experiments have been performed to observe these impacts directly. We report here the experimental design and premanipulation year observations of a field study that tests the hypothesis that oyster reefs control the structure and function of tidal creeks in which they are a dominant feature. When complete, this study (known as CREEK) will have compared ecosystem-scale differences among eight tidal creeks before and after the removal of oysters from four of the creeks.

MATERIALS AND METHODS

Environmental Setting

The observations used in this investigation are from a group of tidal creeks located in the near pristine North Inlet marsh–estuarine ecosystem. North Inlet (33° 20′ N, 79° 10′ W) is located near the city of Georgetown on the northeastern coast of South Carolina, USA. The approximately 3,400 ha system is composed of salt marshes dominated by *Spartina alterniflora* (2,500 ha) and tidal creeks with intertidal oyster reefs (850 ha). A coastal maritime

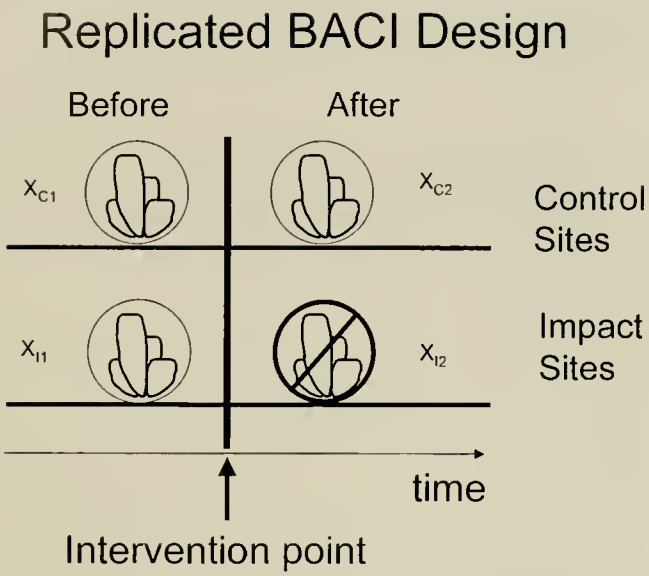

Figure 1. A graphical representation of the Before–After Control–Incident (BACI) statistical design.

forest borders the estuary and generates intermittent freshwater streamflow from approximately 1,000 ha. The climate of the area is subtropical, with average water temperatures ranging from 8 °C in January to 30 °C in July and August. The system is subject to semidiurnal tides, with an average range of 1.5 m. North Inlet has no salinity stratification and usually has very little freshwater input. Owing to shallow water depths and vigorous tidal exchange, creeks in North Inlet are well mixed and nearly always vertically homogeneous with respect to dissolved substances.

Statistical Considerations

We use a replicated BACI (Before-After Control-Impact) design (Fig. 1), with eight similar tidal creeks as replicates. Creeks were assigned to one of four blocks based on their physical locations within the estuary and suspected or known spatial differences at this scale. Blocking was deemed important because Clambank Creek creeks drain an upland area; whereas, Town Creek creeks do not border any uplands, and because there is a salinity gradient from north to south with those creeks further south more likely to experience low salinity spillover from Winyah Bay during freshets. The Before manipulation year began in March 1997 and ended in February 1998. The After manipulation year began in March 1998 following the removal of oysters from four randomly selected creeks, two each in Clambank Creek and Town Creek. Thus, the CREEK study satisfies a number of concerns raised by Hurlbert (1984): (1) there are control creeks; (2) the creeks are replicated; and (3) the creeks are sampled repeatedly, both before and after the intervention. In addition, the design heeds the recommendation of Stewart-Oaten et al. (1986) by sampling all creeks simultaneously. The statistical analysis after the intervention year is an adaptation of Stewart-Oaten et al.'s (1986) proposed analysis. This paper describes only the before or premanipulation year to highlight system variability and to identify potential sources of that variability.

Creek Geomorphology

The eight tidal creeks used in this study are located on two larger order creeks, Town Creek and Clambank Creek, and are within 1 km of each other (Fig. 2). The observed creeks are typically ephemeral (i.e., dry at low tide). A detailed topographic–bathymetric survey of each creek and its basin was conducted

Figure 2. An areal depiction of the study area.

TABLE 1.

Structural dimensions of the eight experimental tidal creeks.

Dimension	Creek							
	1	2	3	4	5	6	7	8
Length (m)	177	101	164	229	138	232	174	423
Length w/tributaries (m)	359	169	284	254	153	306	309	517
Width at mouth (m)	7.6	5.8	6.7	4.6	4.9	3.1	6.7	9.5
Cross-sectional area at mouth (m^2)	5.4	3.2	4.7	2.5	2.5	2.6	4.8	5.7
Water volume (m^3)	667	321	527	520	446	391	623	1,423

utilizing a Topcon total station. All elevations were referenced to a common datum that, in turn, was referenced to eight U.S. Geological Survey permanent benchmarks. The data were used to estimate creek length, width, cross-sectional area at mouth, surface area, and water volume.

Physical and Chemical Variables

Beginning in early March 1997 and continuing until late February 1998, water samples were taken once a week from each study creek for chemical analysis. The samples were taken approximately midway between the daytime high and low tide stages. Water samples were taken from the center of each creek mouth at a depth of 1 m below the surface but not closer than about 0.3 m from the bottom. Triplicate samples were collected from each creek, and all creeks were sampled within 45 min. The samples were immediately placed in ice and rushed to the laboratory for analysis. Temperature was measured at each site as samples were collected. Salinity and concentrations of ammonium, nitrate + nitrite, orthophosphate, and chlorophyll *a* were determined using standard techniques. All water chemistry parameters were logarithmically transformed to ensure equal variability, but temperature and salinity observations were not transformed. The Grubbs test (Grubbs and Beck 1972) was used to determine outliers; only two observations were deleted.

Plankton and Microbial Loop Observations

The planktonic food web in the experimental system was examined using a series of bioassay experiments. These studies were conducted at a morning mid-ebb tide on five dates (March 20, June 13, July 27, September 13, and December 9) in 1997. Replicate samples were collected at each of the eight experimental creeks and dispensed into 1-L acid-cleaned polycarbonate bottles. Samples were incubated under various treatments designed to examine the effect of substrate enrichment or reduced grazing pressure on phytoplankton community biomass (chlorophyll *a*). The treatments included 4 μm NH_4 addition, 20 μm glycine addition, and a 20:1 dilution treatment used to reduce grazing pressure on phytoplankton by decreasing encounter rates between microzooplankton and phytoplankton prey (Landry and Hassett 1982). Lewitus et al. (1998) have found, from experiments involving serial

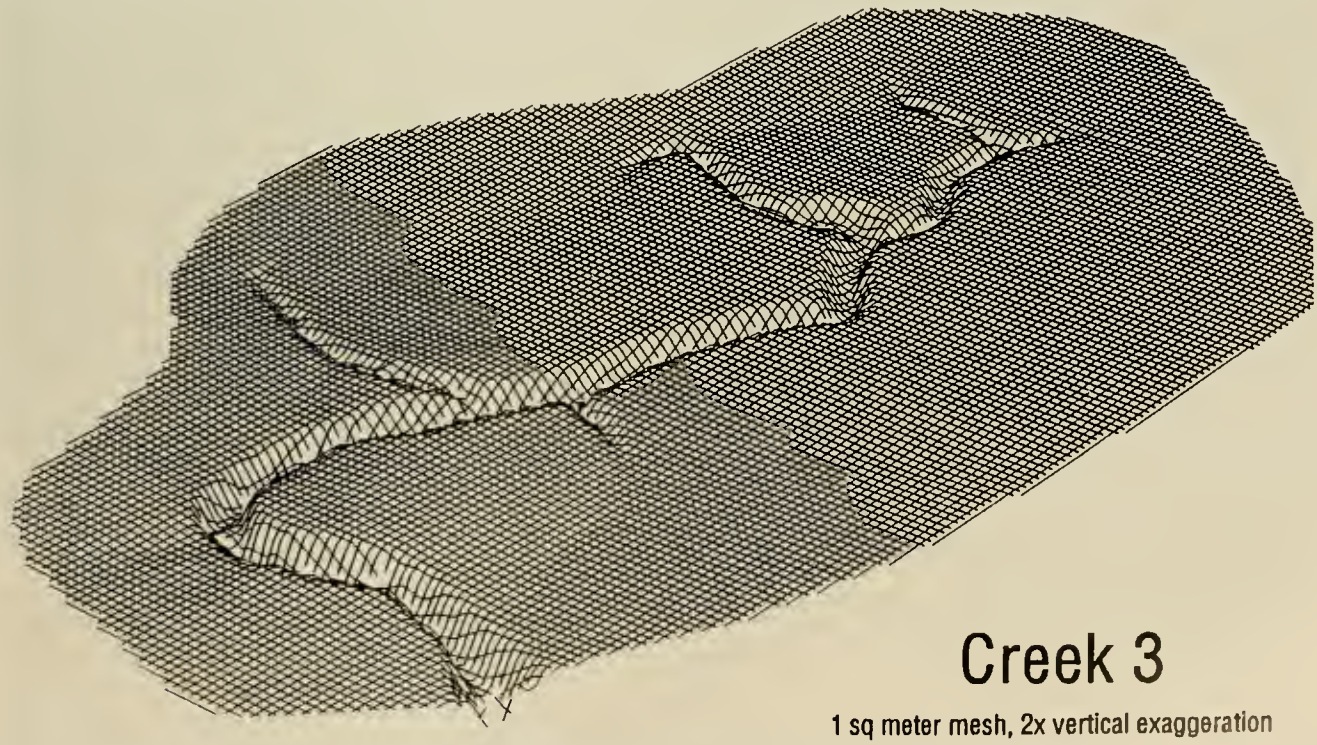

Figure 3. An example of a 3-D surface plot for Creek 3 showing geomorphological relief.

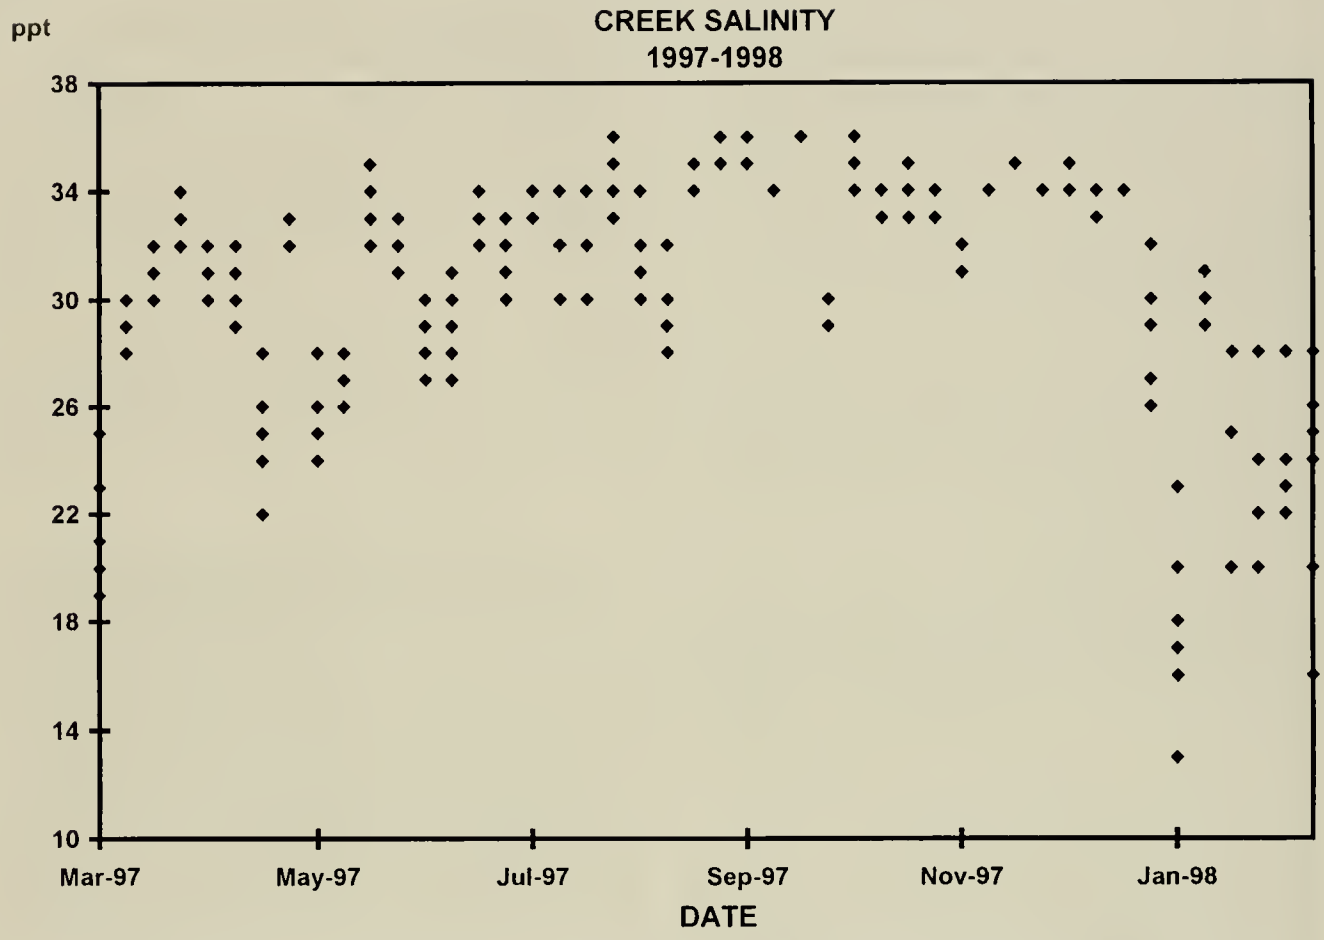

Figure 4. Time plot of salinity data (ppt) from the eight experimental tidal creeks during the premanipulation year of 1997 to 1998.

dilution of North Inlet water, that a 20:1 dilution fell within the range where grazer reduction over 72 hours was saturated. Bottles were incubated in raceways containing flowing estuarine water to simulate tidal creek temperatures. Overhead fluorescent cool white bulbs provided uniform irradiance adjusted to a light–dark cycle simulating natural conditions. Water samples were mechanically stirred (gently) at uniform rates between bottles. Chlorophyll *a* was measured daily at midday over the 72-hour time course.

Nekton Abundance and Biomass

Nekton abundance and biomass were determined for each creek in March, June, August, and November of 1997. Simultaneous collections of nekton were made with block nets set at early morning slack high tide at all eight creek mouths. Catches were removed from the block nets, and pools within each creek bed were seined at low tide to provide a complete assessment of fish and motile macroinvertebrate use of the creeks. All samples were frozen and subsequently sorted to the species level. Total abundance and biomass were determined for each species. Up to 100 individuals of each species were measured to the nearest 2.0 mm. Total wet weight biomass per cubic meter of water volume was the primary unit used to compare catches from creeks with different volumes. A factor of 0.25 was used to convert wet weights to dry weights (Caspers 1957).

Oyster Biomass, Growth, and Survival

Before the premanipulation year observations began, oyster biomass in each creek was estimated from 10 quadrats (0.25 m^2) distributed at different elevations along the length of the creek. Oyster biomass in each creek was adjusted to an average of 8 g dry body weight/m^3 of water. The grams dry body per m^3 relationship was used, because it more realistically describes the benthic–pelagic coupling of the oysters to the water column (Dame 1993). During the premanipulation year, oyster growth and survivorship were observed by placing plastic-mesh bags containing 25 marked and measured oysters in each of the eight experimental tidal creeks. Because the creeks are ephemeral, and tidal exposure is a critical factor in bivalve physiology, bags were placed at four locations approximately equidistant along the mainstem of each creek at approximately the same measured elevation. Summer observations were made between July and October and fall—winter observations were from October to February. Growth was measured as change in length, measured to the nearest 0.1 mm. Biomass to length relationships determined by Dame (1972) were used to calculated dry body biomass.

RESULTS

Creek Geomorphology

The detailed topographic–bathymetric survey of each of the experimental creeks was used to generate longitudinal profiles, hypsometric curves, storage curves, and 3-D surface maps. The results of these surveys are summarized in Table 1, and an example of a 3-D surface map is given in Fig. 3. The creeks range in length, including branches, from 153 to 517 m, and bankfull water volume

ranges from 231 to 1,423 m^3 (Table 1). The surface-t- volume ratio by creek ranged from 1.3 to 2.6. There was less than an order of magnitude difference for any measure between creeks.

Physical Environment

Temperature ranged from 8 to 35 °C and displayed a well-defined seasonal trend. Analysis of variance (ANOVA) of all temperature observations shows that date (time) explains 99.2% of the variation in these data ($P < 0.01$). Salinity data ranged from 12 to 36 ppt (Fig. 4). There was a distinct period of lower and more variable values in all creeks during the December 1997 to March 1998 period. While 91.1% of the variability in the salinity observations were attributed to date, a significant ($P > 0.01$) amount of variability (1.1%) was attributable to creeks.

Water Chemistry

Chlorophyll *a* concentrations range from near zero in the winter to about 42 μg/L in the summer, and depict an annual curve when plotted (Fig. 5). Results of the ANOVA of the premanipulation year data show that 91.6% of the total variability was attributable to time of year and 3.8% was related to creek differences. There were significant differences among dates and blocks of creeks, but not among creeks within blocks. Ammonium concentrations are shown in Figure 6. Values are near zero in autumn and winter and are near 7 μm/L in spring and summer. ANOVA revealed that about 84% of the variability was attributable to date and 4.4% was attributable to creek. Blocks of creeks were not significantly different; however, there were cases where creeks within blocks were different. Phosphorus concentrations were low (near zero to about 1.5 μm/L), with maximum values in summer and minimum in winter. Concentrations of nitrate + nitrite were also low (near zero to 2.7 μm/L), with maximum values and variability in winter and spring. ANOVA showed that variability of nitrate+nitrite and phosphate was similar, although less of the variability in nitrate+nitrite was explained.

Plankton

The seasonal patterns exhibited by chlorophyll *a* in response to NH^4 addition, glycine addition, or dilution were generally similar among creeks (Figs. 5 and 6). For water collected from March to July, the addition of NH_4 occasionally stimulated chlorophyll *a* concentrations in the water from Clambank tributaries (creeks 1–4) but not Town Creek tributaries (creeks 5–8), which is consistent with the lower ambient NH_4 concentrations in the former group (Fig. 7). During the summer months, the Town Creek tributaries averaged higher concentrations of NH_4 than those of the Clambank

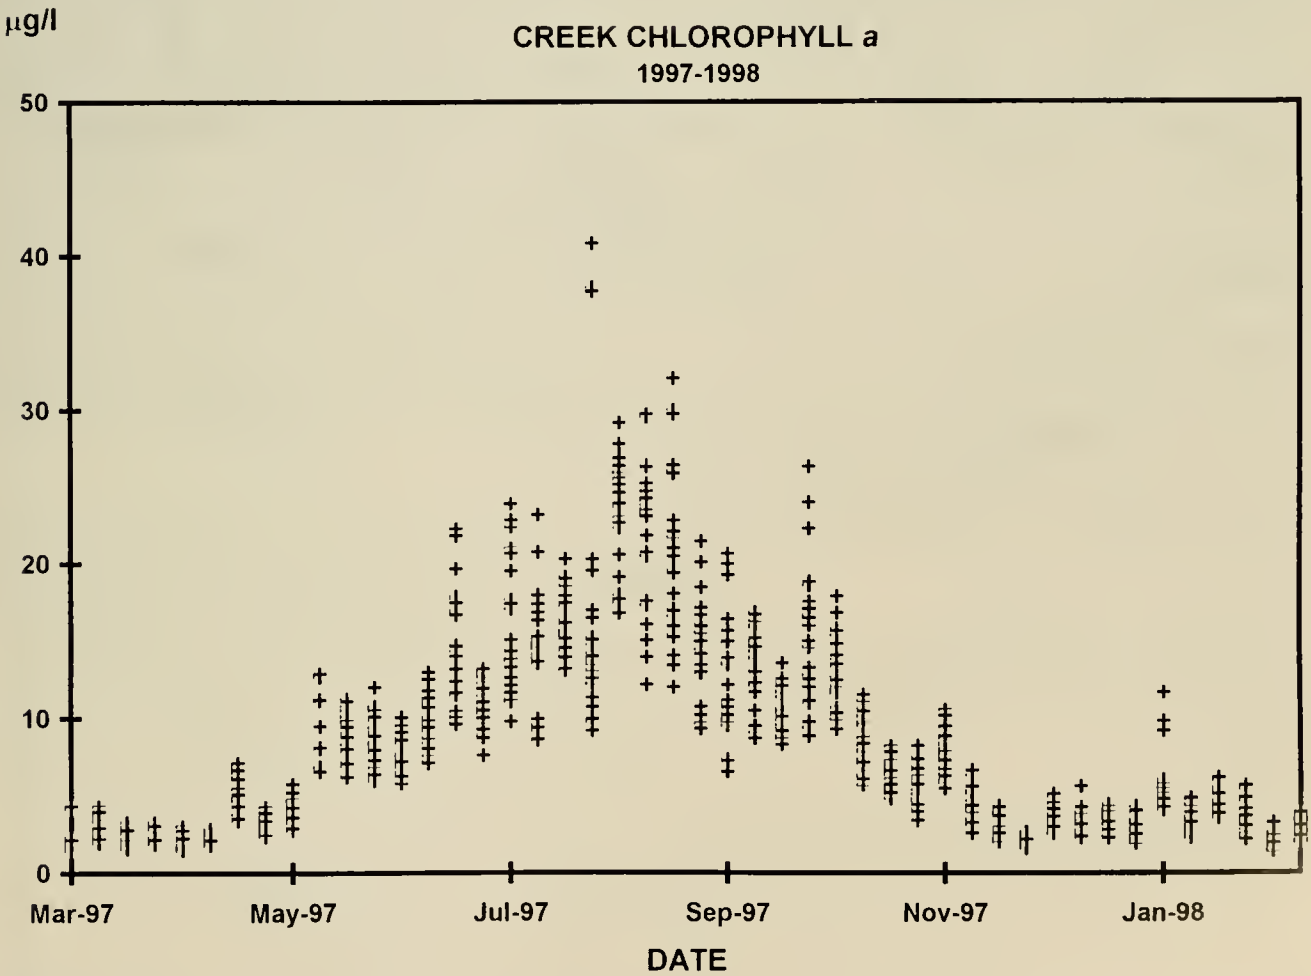

Figure 5. Time plot of chlorophyll *a* concentrations (μg/L) from the eight experimental tidal creeks for the premanipulation year of 1997 to 1998. (triplicates shown).

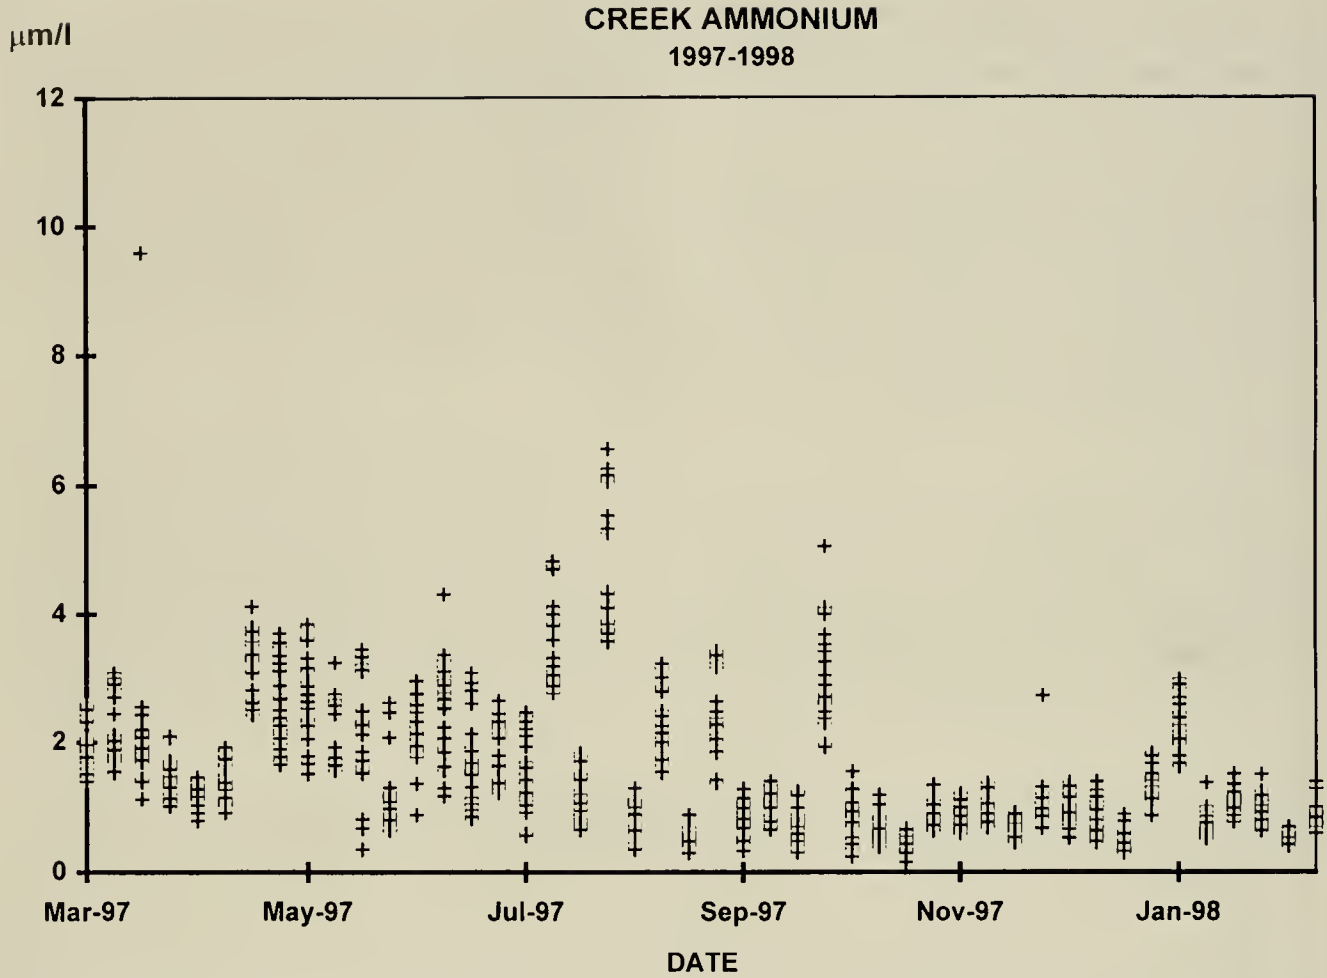

Figure 6. Time plot of ammonium concentrations (µm/L) from the eight experimental tidal creeks for the premanipulation year of 1997 to 1998. (triplicates shown).

tributaries. Dissolved organic carbon (DOC) concentrations were lower in the Town Creek group during this same period.

In almost all cases, the dilution treatment led to greater stimulation of chlorophyll production than either of the substrate additions. The dilution effect was greatest in the summer when nanophytoplankton dominated the community and minimal during the winter and early spring when a microplanktonic diatom-dominated community regulated by nutrient availability was prevalent (Fig. 8).

Oysters

Oyster growth was higher in summer than in winter and was not significantly different between creeks (Fig. 9). Oyster survivorship was higher in winter than summer, and no significant differences between creeks were evident (Fig. 10).

Nekton

Seasonal variations in total nekton biomass were consistent among creeks. Biomass was highest in all creeks during the summer (Fig. 11). Lowest biomasses were observed in March, when water temperatures and salinities were lowest. During the summer months, nekton biomass is generally equal to or as much as five times greater than oyster biomass; whereas, the reverse is true in winter. More than 60 species of fishes, shrimps, and crabs (mostly young of the year) were identified. Seasonal shifts in species dominance were strong and consistent among creeks. Each season, the same creeks supported the highest or lowest nekton densities. These differences seem to be related to geomorphological differences among the creeks.

DISCUSSION

The choice of the appropriate statistical methods for detecting trends and perturbations in ecosystems has been a lively area of debate in the ecological literature (Hirsch et al. 1991). Green (1979) proposed a multifactor ANOVA approach for detecting changes in a single stream for which there are observations upstream and downstream of the perturbation. Green's design was criticized by Hurlbert (1984) for lacking spatial and temporal replication. Hurlbert introduced the term pseudoreplication to describe multiple measurements of a single study site versus what he considered true replication: measurements of multiple study sites at multiple time points. Stewart-Oaten et al. (1986) refined Green's (1979) approach by proposing that the difference between control and impact or manipulated sites measured at multiple time points before and after the manipulation was the appropriate response variable for analysis. They called this approach BACI.

Although salinity observations seem to provide evidence of the strong interannual ENSO climatic event of 1997 to 1998, the temperature data only reflect a normal seasonal pattern. ENSO events

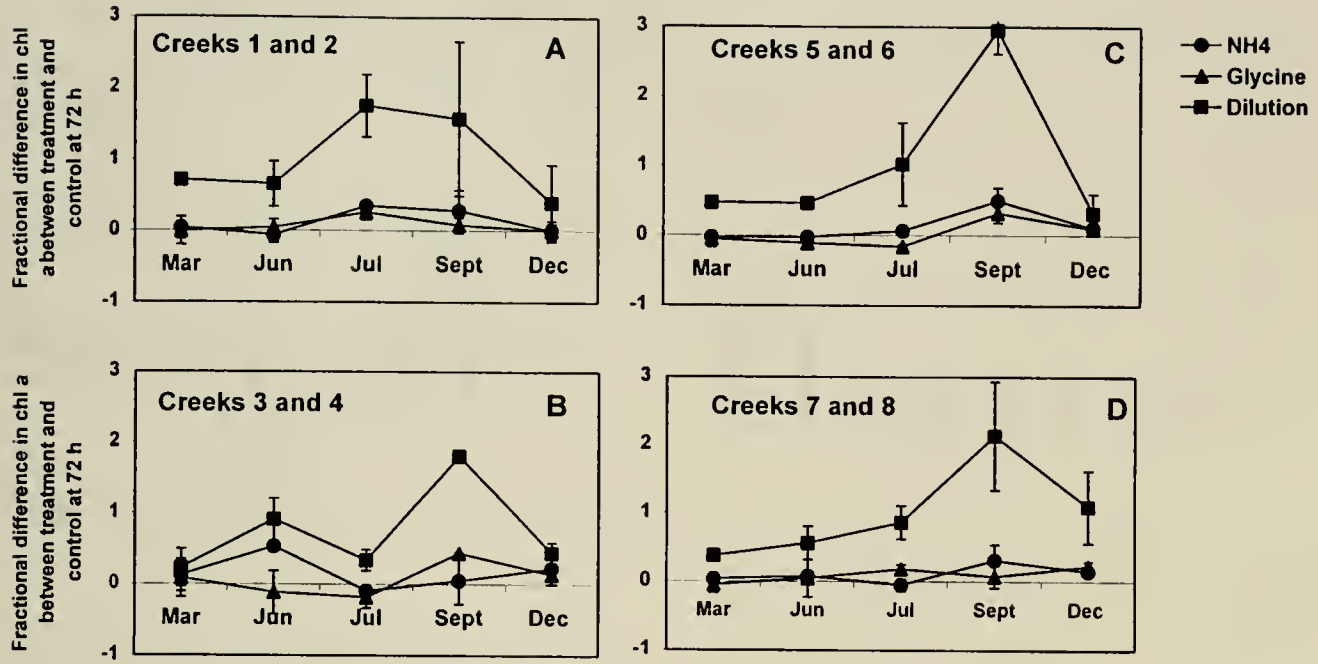

Figure 7. Results of addition and dilution incubation experiments on the planktonic community in the eight experimental creeks during the premanipulation year 1997 to 1998. A value of 0.0 indicates no difference in chlorophyll *a* between experiment and control after 72 hours of incubation, and a value of 1.0 indicates a 100% increase in chlorophyll *a* in the experiment.

are thought to influence the southeastern Atlantic coast by increasing winter precipitation and decreasing air temperatures (Ropelewski and Halpert 1986, Philander 1990, Hanson and Maul 1991). Although higher than normal freshwater discharge to southeastern estuaries with a higher groundwater table should be expected during these events, these features were only statistically observed from the northeastern coast of South Carolina to Florida (Kuhnel et al. 1990). During the 1997 to 1998 El Niño, the coastal zone of the Carolinas received over 200% of normal precipitation for this period. In North Inlet, a normally euhaline estuary, the increased rainfall depressed salinities below 15 ppt for one 3-week period during the December 1997 to March 1998 period. It is probably this precipitation that depressed salinities and increased the variability of our salinity observations during the winter period.

Chlorophyll *a* concentrations are a measure of the major phytoplanktonic food source of the dense oyster populations within North Inlet. The data in Figure 5 are similar to those reported previously for North Inlet (see Lewitus et al. 1998). There seems to be a seasonal transition in the microbial food web structure and regulation, from a microplanktonic diatom-dominated community regulated by nutrient supply during the winter to a nanoflagellate-prevalent phytoplankton bloom regulated by microzooplankton grazing in the summer (Fig. 7). The generally consistent lack of a nitrogen response by the phytoplankton strengthens the possibility that oyster removal may lead to nitrogen limitation.

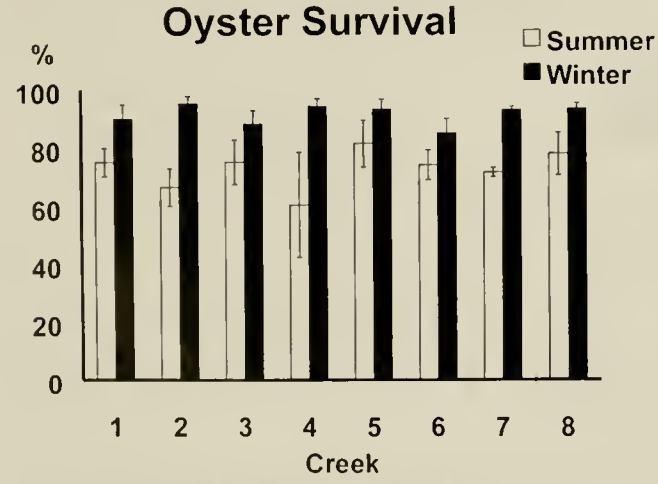

Figure 10. Summer and winter oyster survival in the experimental creeks during the premanipulation year 1997 to 1998.

Ammonium is the major inorganic nitrogen source in North Inlet, because the estuary is a bar-built, high-salinity salt marsh with little freshwater input. This form of inorganic nitrogen is also a major excretory product of oysters and, thus, a major component in the regeneration of nitrogen in this system (Dame 1993). Nitrogen is typically limiting in many coastal and estuarine systems (i.e., there is an inverse relationship between nitrogen and chlorophyll during the bloom period); however, this is not the case in North Inlet. In historical data from North Inlet (Lewitus et al. 1998), and in the data presented here, there is a positive correlation between chlorophyll *a* (Fig. 5) and ammonium (Fig. 6) concentrations. This relationship suggests that ammonium is not limiting during the summer bloom and that other factors, such as grazing, are important (Lewitus et al. 1998). Concentrations of nitrate + nitrite are elevated during the same winter period as reduced salinities, suggesting terrestrial runoff as a source and nutrient limitation as a control on the winter phytoplankton.

Although nekton use of the intertidal creeks was not uniform in space or time, the occurrence of spatially stable patterns suggests that temporally stable features of the physical habitat were important determinants of use. Geomorphological and associated hydrographical features of intertidal creeks may be key attributes of habitat quality as it relates to the nursery function of salt marsh channels. High nekton biomass may, in turn, exert significant influences on water quality criteria that affect the creek system (i.e., NH^4 concentrations). The equivalent magnitudes of nektonic and oyster biomass within these tidal creeks implies that there may be a much more complicated and hitherto unforeseen control of nutrient cycling within these systems.

The premanipulation year studies reported here show that: (1) annual and interannual environmental cycles are evident; (2) no two creeks are the same, but they are all similar in that 85% of the observed variability was explained by date; (3) the plankton community exists in two states, which are regulated differently; (4)

oyster growth and survivorship are normal; and (5) nekton are much more important than previously thought and may match oysters in their influence on tidal creek systems. These observations will certainly be elucidated by the results of the postmanipulation (oyster removal) year.

ACKNOWLEDGMENTS

The authors express their gratitude and heartfelt thanks to all of the students and volunteers who have participated in this project. Their efforts, energy, and stimulus were invaluable. The project was supported by an award (number DEB-95-0957) from the National Science Foundation. This is publication No. 1209 of the Belle W. Baruch Institute for Marine Biology & Coastal Research.

ABSTRACT Oyster reef restoration, protection, and construction are important to meeting harvest, water quality, and fish habitat goals. However, the strategies needed to achieve harvest and conservation goals have often been considered to be at odds. We argue that these goals are, in fact, compatible and that the same strategies will promote a sustainable harvest of the resource, increased filtration of estuarine waters, and increased provision of structured habitat for finfish, crabs, and other organisms that utilize oyster reefs or receive benefit indirectly from them. Creation or designations of unharvested sites (refuge sites) are key components of these strategies. Unharvested reefs have the potential to provide vertical relief, which is typically destroyed by harvest practices, to act as a source of larvae, which potentially increases the supply of harvestable oysters, and to protect those individuals most likely to have some resistance to disease. Furthermore, proper monitoring and design of refuge and restoration efforts are critical to providing information needed to improve the success of future restoration efforts, and will simultaneously enhance the basic information needed to understand the ecology of oysters and their role in estuarine and coastal systems.

KEY WORDS: oyster reef, restoration, water quality, harvest, fish habitat, *Crassostrea virginica*, sanctuaries

INTRODUCTION

Oyster reef restoration is a recognized need by resource agencies in most states along the Atlantic and Gulf of Mexico coasts of the United States. In general, the initial impetus for these programs has been declining harvests and standing stocks of oysters that are at an all time low (MacKenzie et al. 1997a, MacKenzie et al. 1997b, Luckenbach et al. 1999, Coen and Luckenbach 2000 and references therein). Although numerous factors have been implicated in these declines, a consistent factor has been the destruction of reef habitat during the harvesting process (Hargis and Haven 1999, Lenihan and Micheli 2000). To date, most oyster restoration programs have focused on improving oyster habitat as a means of enhancing the commercial fishery (Luckenbach et al. 1999, Coen and Luckenbach 2000). Harvest of oysters involves removal of the reef substrate and, therefore, a decrease in available settlement and growth habitat for subsequent recruits to the oyster population. In addition, most harvesting practices are destructive to the reef matrix, reducing the vertical relief and damaging structural integrity in excess of that caused by removal of the individual oysters actually marketed (Hargis and Haven 1999, Lenihan and Micheli 1999). Shell repletion programs attempt to mitigate this habitat removal and destruction by adding shell as substrate for settlement of oyster larvae. A consequence of these repletion efforts has been a shift toward put-and-take fisheries (Coen and Luckenbach 2000).

Recognition of oyster reefs as valuable estuarine habitats that provide a range of ecosystem services is increasing (Coen and Luckenbach 2000, Coen et al. 1999b). The original goal of restoring and enhancing fishery stocks has been augmented, and in a few instances, superceded, by two additional goals: (1) improving water quality (by removing a portion of the phytoplankton standing stock) and (2) providing a structured habitat that may increase

secondary production, including production of finfish and decapod crustaceans, such as crabs (Fig. 1) (Wenner et al. 1996, Coen et al. 1999a, Coen 1999b). Extrapolations from laboratory filtration rates (Newell 1988, Powell et al. 1992), direct field measurements (Dame 1996 and references therein), and ecosystem-level modeling (Ulanowicz and Tuttle 1992) have clearly demonstrated that oyster reefs can have significant impacts on material processing and energy flow in estuarine systems. The recognition of the importance of oysters' ability to reduce phytoplankton biomass as a result of their filtering capabilities coincides with an increased concern over eutrophication in coastal waters. Increased anthropogenic loadings of nutrients make the ecosystem-level role of suspension feeders (such as oysters) all the more critical at the same time that overharvest and disease have reduced populations through much of their range.

Furthermore, descriptive and experimental studies have pointed to the importance of oyster reefs as habitat for commercially and ecologically important finfish and decapod crustaceans (see Wells 1961, Bahr and Lanier 1981, Stanley and Sellers 1986, Breitburg 1992, Breitburg 1999, Wenner et al. 1996, Coen et al. 1999a, Coen 1999b, Harding and Mann 1999). Although few specifics are known about the relationships among oyster reef structure, oyster population structure, and the provision of these ecosystem services, it is likely they are related to the vertical relief of reefs, the size and numbers of reefs, the overall estuarine habitat landscape, habitat health, and the population density and age structure of oyster populations. Seemingly, this sets up a conflict between the goals of fisheries exploitation and those of ecological restoration and conservation. With recent revisions to the Magnuson–Stevens Fishery Conservation and Management Act (1996) this conflict might be expected to intensify (Coen et al. 1999b).

In this paper, we address the challenge of simultaneously achieving all three goals of oyster reef restoration (fisheries, water quality, and habitat), highlight ecological processes that may make the feasibility of meeting all three goals more or less difficult, and discuss the potential benefits of melding research and restoration activities. We emphasize our belief that these goals are generally compatible and the importance of keeping all three goals in mind to achieve sound habitat and resource management and restoration. Many of the ideas in this paper stem from discussions at the special session and workshop on oyster reef restoration organized by L. Coen and M. Luckenbach at the 2nd International Conference on Shellfish Restoration held in Hilton Head, South Carolina, in November 1998. Our intent is to summarize some of the major themes and explore the constraints associated with sustaining the goals of fisheries exploitation and habitat conservation, not to provide a comprehensive review of the workshop and presentations or to address all of the issues related to oyster restoration raised therein.

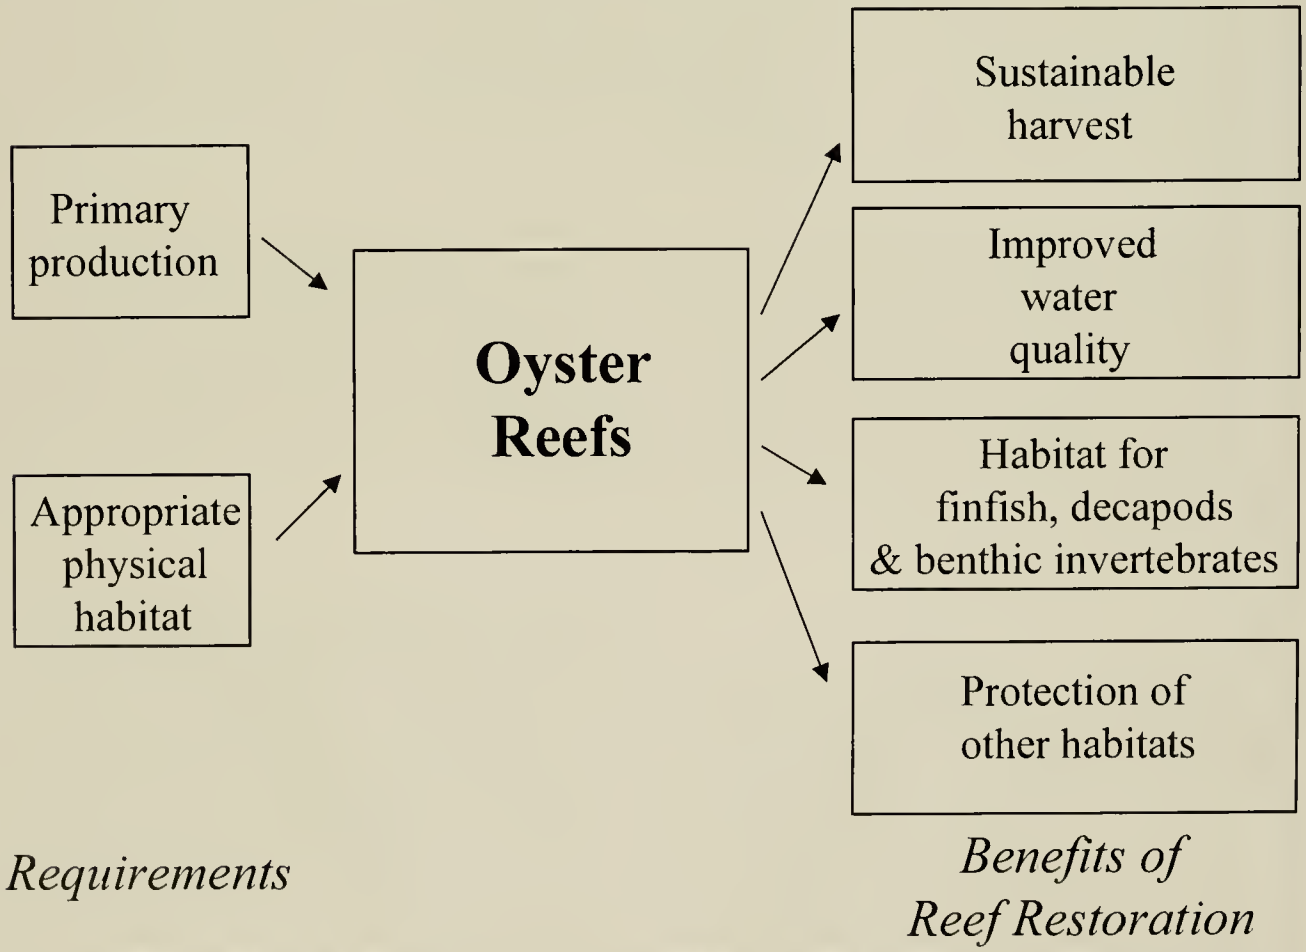

Figure 1. Restoration of oyster reefs has three primary goals: increasing sustainable harvests of oysters, improving water quality through the removal of phytoplankton biomass, and increasing structured habitat utilized by finfish, crabs, benthic invertebrates, and (especially for intertidal reefs) birds. In addition, studies by Meyer and colleagues indicate the possibility that oyster reefs can play a significant role in reducing shoreline erosion and protecting salt marsh habitat (see Meyer et al. 1996, Meyer et al. 1997).

Although many areas of uncertainty remain, we believe a pattern of convergence is emerging (see recent reviews by Lenihan and Peterson 1998, Coen et al. 1999b, Luckenbach et al. 1999, Coen and Luckenbach 2000).

COMPATIBILITY OF HARVEST AND ECOLOGICAL GOALS OF OYSTER REEF RESTORATION

Are sustainable harvest and ecological goals of oyster reef restoration compatible? The relationships between production and biomass, as well as between the fishery and ecological benefits of unharvested refuge areas, contribute to our belief that the answer is yes. Figure 2 illustrates the possible relationships between production and biomass. Maximum production of a resource is achieved at a biomass lower than the maximum potential biomass because of processes ranging from self-shading in phytoplankton, to age-dependent growth declines, to prey depletion that occurs at high population densities of consumers. In part, the degree to which harvest and ecological values of reefs coincide will depend on which of the family of curves depicted in Figure 2 best describes estuarine oyster populations. Maximum sustainable yield strategies in fisheries generally focus on keeping a population near its maximum rate of production but on the descending portion of the curve (i.e., biomass greater than that at maximum production), where overharvesting of the resource is less likely to occur than along the ascending portion of the curve (see Applegate et al.1998, Restrepo et al. 1998 for a comprehensive discussion of these curves in a fishery management context). Because maximum filtration rates and maximum production are both related positively to per capita growth rates (Powell et al. 1992, Hoffman et al. 1995), population densities producing high levels of sustainable harvests should also be those that lead to a high (possibly maximal) ecological benefit of water filtration by oysters. Finally, although less well understood, we argue that "more is better" in terms of the habitat oysters provide for fish, crabs, and other benthic organisms, but, as with the other goals, there is a decreasing benefit portion of the curve. Something short of complete coverage by oysters is needed to produce a diversity of benthic habitats that includes soft bottom, submerged aquatic vegetation, salt marsh, oyster reefs, and clam beds, where these have naturally or historically co-occurred. As important, many fish and decapods orient toward the edges of reefs and do not simply utilize the large interior areas (Powell 1994, Breitburg 1999). It is critical to keep in mind that even if the optimal biomass for harvest and ecological goals do not coincide precisely, movement toward all three goals requires increasing oyster biomass in most estuarine systems.

The more the production versus biomass curves are skewed to the right (e.g., curve C rather than curve A in Fig. 2), the higher will be the optimum oyster standing stock for a sustainable fishery and the greater will be the coincidence between biomass levels optimizing the filtration capacity of the oyster population and the provision of habitat for other biota. Several features of oyster biology, as well as ecological interactions among oysters, the

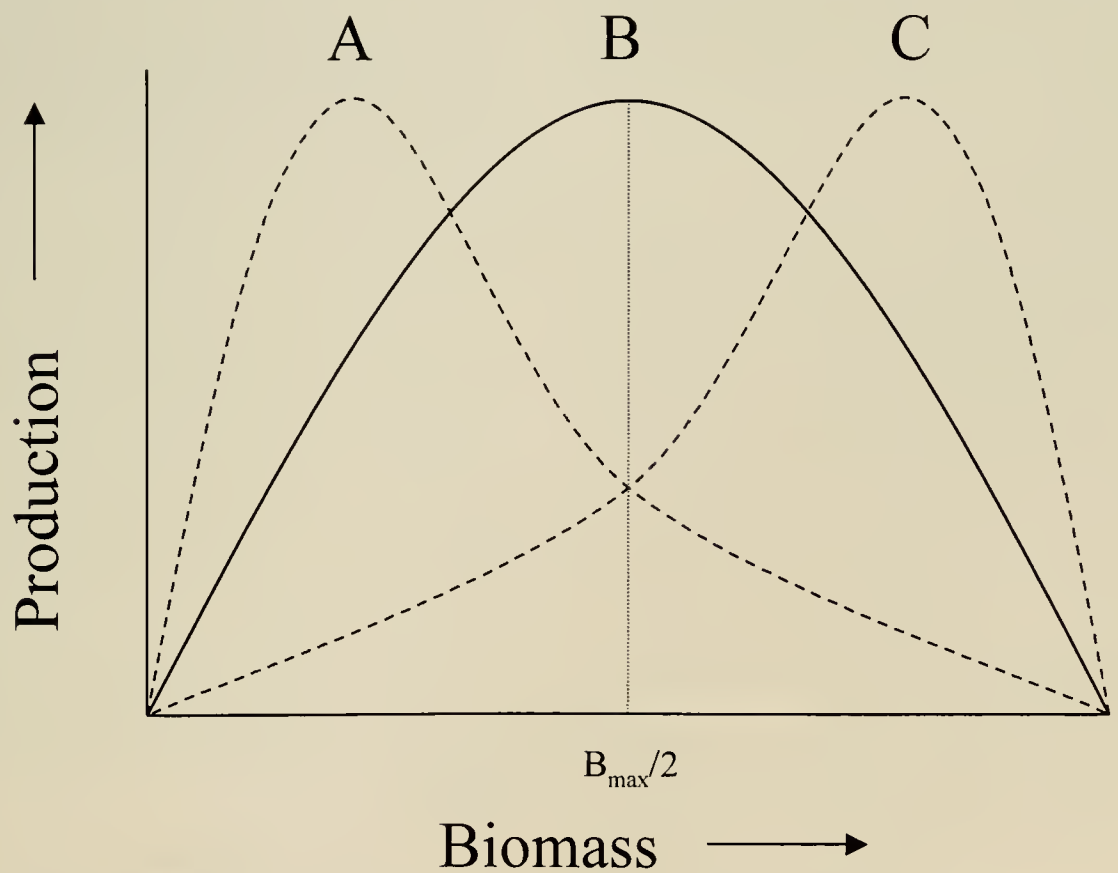

Figure 2. Relationship between production and biomass. Theoretical considerations suggest that maximum production will often occur at one half the maximum biomass (Applegate et al. 1998). However, interference competition and resource depletion can skew the curve to the left (A), and increased efficiency or reproductive success at high densities can skew the curve to the right (C). We suggest that under most conditions, oyster populations will be described by curves B or C, making harvest, water quality, and habitat restoration goals compatible.

physical environment, and other biota suggest a high-biomass–high-productivity relationship, with greatest success for all three goals occurring with well-developed or "mature" high-relief reefs. High density within oyster beds is likely the optimal condition for the oysters themselves, because the preferred settlement substrate for oyster larvae is oyster shell (e.g., Hidu 1969, Luckenbach et al. 1997, Bartol and Mann 1999), the fertilization success of sessile animals is increased at high densities (Levitan 1991, Levitan et al. 1992), and the subtidal reefs will maintain greater vertical relief, reducing sedimentation effects and enhancing local flow rates (Lenihan and Peterson 1998). High aerial coverage by oysters should provide insurance against the strong spatiotemporal variability in physical and biotic factors that can influence both spat set and the health of adults (Lenihan and Peterson 1998). For systems with limited water exchange and/or small tidal creeks with relatively large tidal ranges (> 1–2 m), minimum reef area may be essential for maintenance of local populations. In more open systems, increased cover may provide a buffer against local disturbances and recruitment variability.

IMPORTANCE OF HARVEST REFUGES

Unharvested (refuge) areas are critical to achieving both harvest and ecological roles of oyster reefs. Refuge areas protect brood stock and, as a result, can enhance oyster populations in surrounding harvested areas that are many times the size of the refuge itself (Wesson 1998). Moreover, in areas affected by oyster diseases, refuges provide protection for individuals that may have some resistance to disease. In harvested areas, the largest oysters, which are the individuals that have survived in the presence of disease pressure and have the highest fecundity, are the ones culled from the population (Rothschild et al. 1994, Coen et al.1999b). Protecting some reefs from harvest should, therefore, serve to enhance the vigor of stocks.

In addition, harvest-free sanctuaries allow reefs to develop and retain vertical relief and structural complexity that are important to both oysters and associated fauna. Vertical relief can provide oysters with the means to avoid near-bottom oxygen depletion and high sedimentation rates, and to take advantage of increased flow velocity and enhanced growth rates (Lenihan et al. 1996, Lenihan and Peterson 1998, Lenihan et al. 1999). In addition to reef elevation, vertical complexity of the reef itself (i.e., the presence of high culms interspersed with low areas) enhances fish and decapod utilization (e.g., Breitburg et al. 1995, Breitburg 1999, Coen et al. 1999b, Harding and Mann 1999, Posey et al. 1999, Coen and Luckenbach 2000) and may protect oyster spat from predation (Wesson 1998, unpubl. data, Giotta and Coen 1999). Because harvesting reduces vertical complexity, these habitat functions may benefit from creation of unharvested (refuge) areas (Coen et al. 1999b, Lenihan and Micheli 1999). However, there is also a view that some thinning may enhance intertidal oyster populations (Lenihan and Micheli 1999, W. Anderson, South Carolina Department of Natural Resources, pers. comm.).

Refuges also provide a tool at the landscape level that allows reefs to be placed in areas that are protected or closed to harvest and that will maximize desired functions (reviewed in Lenihan and Peterson 1998, Coen et al. 1999b, Luckenbach et al. 1999, Coen and Luckenbach 2000). For example, low-salinity refuge areas in the Maryland portion of the Chesapeake Bay are designated to protect oyster brood stock in areas generally unaffected by either *Perkinsus* (Dermo) or *Haplosporidium* (MSX) (Bushek and Allen 1996a,b, Paynter 1999, Coen and Luckenbach 2000). Similarly, designated areas closed to direct harvesting for health reasons may act as refugia as an indirect result of their value as habitat and brood stock reserves (Coen and Luckenbach 1999).

SPATIAL CONSIDERATIONS

There is still much to be learned about the importance of the location of restored oyster reefs within an estuarine landscape (Posey et al. 1998, Coen et al. 1999b). Whitlach and Osman (1999) have developed a metapopulation demographic model of oyster populations that illustrates the importance of dispersal between spatially distinct subpopulations to the persistence of oyster reefs. The foregoing discussion about brood stock sanctuaries and the dispersal of larvae from them to nearby reefs clearly illustrates the importance of reef position within a landscape to the development of reefs and potential fisheries production. Further, the location of reefs will affect the ecosystem services that they provide (see Lenihan and Peterson 1998, Coen et al. 1999b, Coen and Luckenbach 2000). For instance, restoring or constructing reefs in locations key to intercepting waters with high nutrient loadings and the associated high phytoplankton biomass should be possible. Similarly, the proximity to other structured habitat may be important to the function of oyster reefs (Micheli 1997, Coen et al. 1999b). Reefs could be sited in areas with little or no other structured habitat so that they could function as important "stepping stones" or migration corridors along the landscape. Alternatively, if data indicate the advisability of doing so, reefs could be sited in close proximity to other structured habitat to maximize interactions and connections between, for example, submerged aquatic vegetation or salt marsh grass and oyster reef assemblages.

A particularly intriguing ecosystem service provided by constructed oyster reefs adjacent to salt marshes has been discussed by Meyer et al. (1996, Meyer et al. 1997). In addition to providing structured habitat for fauna, these reefs stabilize the creek banks and reduce erosion of adjacent marshes (Meyer et al. 1996, Mayer et al. 1997, Meyer and Townsend 2000). As more information is gathered, the role of oyster reefs in erosion control may be determined to be as important as their other ecological services. Reefs with substantial vertical relief that reach the surface of the water may dissipate much of the energy generated where fetch on open bodies of water allows substantial energy to accumulate.

Regardless of other spatial considerations for oyster reef restoration and creation, several aspects of the placement of reefs within the landscape will influence their success both in terms of reef longevity and their measurable, short-term impact on the surrounding habitat. Successful siting of reefs generally depends upon locating substrate capable of supporting the added shell (without rapid burial), and therefore, generally favors their construction on footprints of historical oysters reefs. In addition, placement of brood stock sanctuaries should consider local circulation to maximize retention and recruitment of resultant larvae. This philosophy has dictated the placement of constructed reef sanctuaries in the Virginia portion of the Chesapeake predominantly in small subestuaries with limited watersheds, small tidal excursions, and basin topographies that encourage gyre-like circulation near the river mouths (Haven et al. 1981, Southworth and Mann 2000, Wesson unpubl. data).

STRATEGIES FOR RESTORATION

The harvest and ecological goals of oyster restoration are most likely to be compatible where management efforts focus on the ultimate goals, and the harvest is managed as a sustainable rather

than a "put-and-take" fishery. For example, targets for the amount of acreage for oyster restoration and protection could be set by determining the volume of water to be filtered within a given time or by determining the ratio of unharvested to harvested area required to sustain a target harvest quantity. We argue that such goal-oriented target setting is more likely to achieve the desired result than setting targets based upon historical oyster populations. Moreover, it is important to consider that restoration efforts proceed one step (i.e., one or a few reefs) at a time and that metrics to gauge the success of these efforts need to reflect both the value of the individual projects and their contribution toward the ultimate goal. For instance, the harvest potential of an individual reef expressed in terms of the biomass that may be harvested sustainably per unit area (rather than as the number of bushels of market-sized oysters in the standing stock) embodies both the productivity of the reef and the total area necessary to achieve the desired harvest levels. Similarly, the fishery value of a protected (unharvested) refuge area based on its potential contribution to harvest in other areas after allowing for a number of years of reef development is a more reasonable assessment of the value of a refuge than would be a simple calculation of the number of acres taken out of the active fishery. Likewise, measures of the ability of a unit area of reef to filter a specified volume of water or to support a specified biomass of finfish, decapods, shorebirds, or other target species will be more useful metrics than attempts to define the contribution of a single reef to the percent of the entire water mass filtered each day or to the biomass of a particular fish within an entire estuary.

LEARNING FROM RESTORATION EFFORTS

Restoration efforts, when properly designed and monitored, present an unparalleled opportunity to improve our understanding of both the optimal design for future restoration efforts and the ecological role of oyster reefs in coastal systems (Table 1). There are two key elements required to maximize the information from restoration efforts. The first is careful planning in the design and siting of reefs to match the restoration efforts with the information desired. For example, in areas such as the northern portion of the Chesapeake Bay and Delaware Bay where subtidal reefs were likely the historical norm, there may be concern that reefs not visible from but near the surface of the water may present navigation hazards. However, constructing reefs in deep water (thus, creating no navigation hazard) can expose oysters and associated biota to low dissolved oxygen concentrations during summer. By constructing and monitoring replicated reefs similar in size and relief (and thus cost) at shallow and deep sites, the optimal depth for reef placement in future restoration efforts could be determined. Simultaneously, important basic information could be gathered on the similarities and differences in the oyster populations and the ecological functioning of deep and shallow oyster reefs. More generally, by designing restoration efforts to allow comparisons between reasonable alternatives, it becomes possible to answer many important restoration questions. These include such questions as: (1) Does the benefit (i.e., growth, recruitment, or survival of oysters) derived from the construction of high vertical relief beds outweigh the costs of constructing such reefs? (2) Do oyster reefs placed near other structured habitats (such as SAV beds or tidal marsh areas) have higher or lower habitat value for finfish? (3) Is the extended "footprint" (i.e., area of increased oyster recruitment surrounding restored reefs) greater near harvested or unharvested restoration sites? (4) Does the addition of juvenile or adult brood stock oysters (either wild or hatchery-reared) increase long-term productivity of a reef sufficiently to justify the costs? (5) Does the benefit of oysters' water filtration

TABLE 1.

Examples of restoration efforts.

Restoration Action	Improvement in Restoration Practices	Improvement in Understanding of Oyster Reef Function
1. Reefs constructed at different depths	Importance of reef depth to successful restoration	Relationship between depth and recruitment, growth and survival of oysters and reef associated biota
2. Reef construction using different base materials	Evaluation of alternative materials for successful restoration	Relationship between construction material and development of oyster populations and reef associated biota
3. Reef construction with varying spatial dispersion patterns	Aid in the placement and spatial arrangement of restored reefs	Evaluation of the role of reef spacing patterns in maximizing oyster recruitment and providing habitat for mobile species
4. Position constructed reefs in varying proximity to other landscape elements	Aid in the placement and spatial arrangement of restored reefs	Evaluation of the importance of reef placement within a landscape for achieving restoration goals
5. Reefs constructed in areas with different tidal ranges and water quality and harvesting status	Aid in the successful restoration and protection of habitats that might otherwise not be protected or restored successfully	Enhance appreciation of EFH or critical habitat roles; provide better understanding of biogeographic differences among sites differing in physical regimes
6. Reefs constructed with varying shapes and vertical structure	Aid in the placement and construction of restored reefs	Evaluation of reef morphology relationships for habitat goals

Restoration efforts can be designed in ways that will provide information critical for improving future restoration work. In addition, they provide the opportunity for large-scale ecosystem manipulations that may greatly improve the understanding of the structure and functioning of coastal systems. The examples of these opportunities in the table are intended to be illustrative, not exhaustive.

capabilities vary with location, depth, habitat type, shape, etc.? (6) How do the shape and vertical complexity of reefs affect habitat function? (7) How do the answers to these and other related questions differ among sites and systems (e.g., intertidal versus subtidal oyster reef habitats, areas with significantly different tidal ranges, etc.)?

The second element required to maximize information from restoration efforts is the necessity for adequate monitoring to evaluate their success (see discussions in Coen and Luckenbach 2000). The specific type and intensity of monitoring will be determined by the goals of any particular restoration effort, the comparisons being made (as above), the target levels being set for improved harvest and ecological benefits, and ultimately the available funding. In addition, evaluation of both the biological impact of reef restoration (both harvest and ecological benefit goals) and the economic considerations may often be important. Experiences from the past several decades with restoration of other marine and coastal habitats consistently point to the need for well-designed monitoring studies to evaluate the success of restoration efforts (see Thayer 1992). As pointed out by Zedler (1992), monitoring to assess success and research that can help clarify how to meet restoration goals, are often not supported adequately by the entities that fund the actual restoration projects (discussed also in Coen and Luckenbach 2000). A significant challenge for oyster reef restoration efforts will be developing potential funding sources to support both large-scale habitat manipulations and long-term monitoring and assessment activities.

By combining carefully planned and targeted restoration efforts with adequate monitoring of the results, it will be possible to obtain information on topics about which little is known. Some of these topics (see also Table 1) are: (1) the characteristics of oyster reefs that are important for transient finfish and crab populations; (2) the area beyond the boundaries of the actual restoration effort in which both oysters and associated biota are affected under a range of hydrographic conditions; (3) the importance of the spatial arrangement of reefs within an estuarine landscape; and (4) the potential for oyster reefs to play a role in reducing shoreline erosion. These are not simply topics of academic interest but relate to the core goal of restoring oyster harvests as a sustainable fishery and minimizing anthropogenic effects to our coastal systems. In addition, among the most critical issues for future restoration efforts may be the questions: Where can sufficient reef substrate be obtained? and What oyster strains should be used to restore areas where oysters have long been in decline? Alternative substrates take on an increasingly significant role, as does the potential problem of introducing nonindigenous species or new disease strains with the importation of oyster shell from other regions (Bushek and Allen 1996a, Busheck and Allen 1996b, Bushek 1997, Coen et al. unpublished, G. Ruiz pers. comm.).

FUTURE STEPS

Despite uncertainties surrounding many aspects of reef restoration, it is important to move forward with restoration efforts; it is clear that reef restoration has the potential to provide strong benefits to both the harvest and ecological functions of oyster reefs in coastal systems. Most important, restoration efforts should target all three functions of natural reefs: harvest, the provision of structured habitat, and the potential for improved water quality. Rather than an adversarial relationship between fisheries and conservation interests in this regard, we suggest there are enough similarities of interests and approaches—especially the desire to optimize the amount and location of settlement substrate—that compatible strategies may be achieved. A critical feature of achieving this compatibility will be clearly expressing the benefits of reef restoration (depicted in Fig. 1), and relating each benefit in a quantifiable way to reef and oyster production.

ACKNOWLEDGMENTS

We thank all participants for the free exchange of ideas that contributed to the interesting and productive symposium and workshop on oyster reef restoration at the 2nd International Conference on Shellfish Restoration. In particular, we thank R. Dame, D. Bushek, and H. Lenihan for comments and input into the organization of the session and associated workshop. Participation by D. Breitburg, M. Luckenbach, and R. Mann was funded in part by the US-EPA Chesapeake Bay Program. South Carolina Sea Grant Consortium provided major funding (#NA46RG0484) for L. Coen. North Carolina Sea Grant provided funding for M. Posey. This is Contribution # 436 from the Marine Resources Research Institute, SCDNR.

ABSTRACT The deployment of oyster shell in estuarine intertidal areas to create habitat for juvenile Dungeness crab (*Cancer magister*) is now used routinely as mitigation for "unavoidable losses" of crab during dredging operations in Grays Harbor and Willapa Bay along the southwest coast of Washington State. Feasibility studies were conducted in 1986 to 1987 for a U.S. Army Corps of Engineers project to widen and deepen the navigation channel in Grays Harbor. Since that time, several studies have elucidated the ecology of crab and other organisms that recruit to the created shell reefs. Studies have also refined the procedures used to calculate crab losses caused by dredging and crab production in the shell habitat. The shell does serve as crab habitat; however, initial assumptions about the longevity of the shell have proved to be overly optimistic, because the shell can sink or be covered with silt before the end of the first summer after deployment. In addition, competition with the shore crab, *Hemigrapsus oregonensis*, has displaced juvenile Dungeness crab. We summarize results of these studies and present initial results from an ongoing mitigation effort that seeks to produce a more persistent living oyster reef in Willapa Bay.

KEY WORDS: Dungeness crab, dredging, mitigation, oyster shell, Washington State

INTRODUCTION

A large project that widened and deepened the navigation channel of Grays Harbor estuary in Washington State, USA (Grays Harbor Navigation Improvement Project, GHNIP) continues to be the impetus for numerous studies on the potential effects of dredging on the environment (USACOE 1982, USACOE 1989). Early on, Dungeness crab (*Cancer magister*, Dana, 1852) was identified as one of the most important species impacted by dredging operations in Grays Harbor (Tegelberg and Arthur 1977, Stevens and Armstrong 1984), and numerous studies were conducted to define those impacts (Armstrong et al. 1987, McGraw et al. 1988, Wainwright et al. 1992).

State and federal agencies directed the U.S. Army Corps of Engineers (USACOE) to minimize the loss of Dungeness crab caused by dredging or to mitigate for unavoidable losses (USACOE 1989). Based on observations that shell deposits found in the intertidal areas of Grays Harbor serve as habitat for newly settled Dungeness crab (Armstrong and Gunderson 1985, Gunderson et al. 1990, Jamieson and Armstrong 1991, Eggleston and Armstrong 1995), an extensive pilot study was conducted to demonstrate that shell deposits could be artificially created by placing oyster shell on the mudflats (Dumbauld et al. 1993). The habitat created was expected to enhance intertidal recruitment and survival of juvenile Dungeness crab and provide an economical means of mitigating for the loss of older, subtidal crab attributable to dredging. The GHNIP was approved and dredging completed in 1990 by removing 10 million m^3 of sediment from the navigation channel in Grays Harbor. To the extent possible within the confines of an economical dredging program (McGraw et al. 1988), the USACOE scheduled dredging operations to coincide with low crab abundance. Nonetheless, impacts occurred, and the USACOE utilized a model to estimate the losses at 100,000 adult equivalents (Wainwright et al. 1992). This represented less than 1% of the estimated crab population, but this loss was significant enough that USACOE was obligated to mitigate for the loss by creating intertidal shell habitat. A series of large shell plots were created on the intertidal mudflats of Grays Harbor from 1992 to 1998 to mitigate for the loss of crab caused by the initial construction of the channel, annual incremental maintenance, and other subsequent dredging projects.

In this paper, we review a pilot study and associated research that led to the current policy of mitigating for the loss of Dungeness crab by creating intertidal shell habitat in Washington State coastal estuaries. Problems are described that continue to be experienced in the implementation of the policy by constructing full-scale shell reefs, and potential solutions that have been developed based on continued research are summarized. We also introduce a more recent project that seeks to mitigate for the loss of crab attributable to a test dredging project in Willapa Bay, Washington. A significant difference in the mitigation strategy for the latter project is the attempt to take advantage of natural oyster recruitment occurring in this estuary. This is designed to create a living oyster reef much like the reefs being restored on the East Coast of North America (discussed elsewhere in this symposium proceedings). Our intent in this paper is to describe a novel approach to creating habitat for a decapod crustacean on the West Coast of North America, and also to highlight the perils and practical les-

sons learned from implementing such large-scale restoration efforts.

PILOT STUDY

Early observations indicated juvenile Dungeness crab recruit to and survive in shell deposits (typically death assemblages from the eastern softshell clam *Mya arenaria* L., 1758) and in aquaculture areas where Pacific oysters (*Crassostrea gigas*, Thunberg, 1793) are raised for human consumption (Armstrong and Gunderson 1985, Gunderson et al. 1990, Jamieson and Armstrong 1991). We conducted a pilot study to test the hypothesis that additional shell placed in the intertidal area of Grays Harbor, Washington, would serve as a refuge for and increase survival of juvenile crab, thereby mitigating for substantial losses attributable to subtidal dredging during construction of the GHNIP (Dumbauld et al. 1993). Oyster shell was placed intertidally at three locations in Grays Harbor (Fig. 1, small plots). At each location, three 15 × 15 m plots were constructed, and treatments were: (1) heavy shell cover (2–3 shell layers thick; (2) light shell cover (one shell layer thick); and (3) shell piles (approximately 1 m in diameter and 0.5 m high). Crab recruited to the shell plots from May to July and by late August grew to fourth–sixth instars (J4–J6, 17–31 mm carapace width, CW), then presumably emigrated to the subtidal. Results indicated that location within the estuary influenced crab abundance and that the three-dimensional configuration of the shell was also important (Fig. 2). Although there was statistical interaction between the location and treatment terms, when low numbers and variable results from the South Bay were removed from the analysis, it was determined that crab density was significantly higher as three-dimensional habitat increased in the sequence: shell piles > heavy shell cover > light shell cover. Subsequent research has shown that the shell habitat provides small crabs refuge from predation and that the thick shell treatment also provides better habitat than eelgrass (Fernandez et al. 1993).

The integrity of the shell habitat was measured 1 and 2 years after shell placement. The heavy shell treatment seemed to survive winter storms and sedimentation better than the piles treatment and crab continued to use the plots in subsequent years, albeit in lower densities. Because the heavy treatment was also the most practical to implement on a large scale, USACOE chose this configuration as part of the preferred alternative in the supplemental Environmental Impact Statement (EIS) (USACOE 1989).

LARGE-SCALE IMPLEMENTATION: PROBLEMS AND LESSONS

Shell Retention

The GHNIP received approval from state and federal agencies and dredging removed 10 million m^3 of sediment from the navigation channel of Grays Harbor in 1990. Results of the pilot study were used to plan for shell mitigation on a large scale. Recognizing the importance of site selection, the USACOE conducted studies in 1990 to 1991 (Armstrong et al. 1992). Three of four 0.4-ha plots

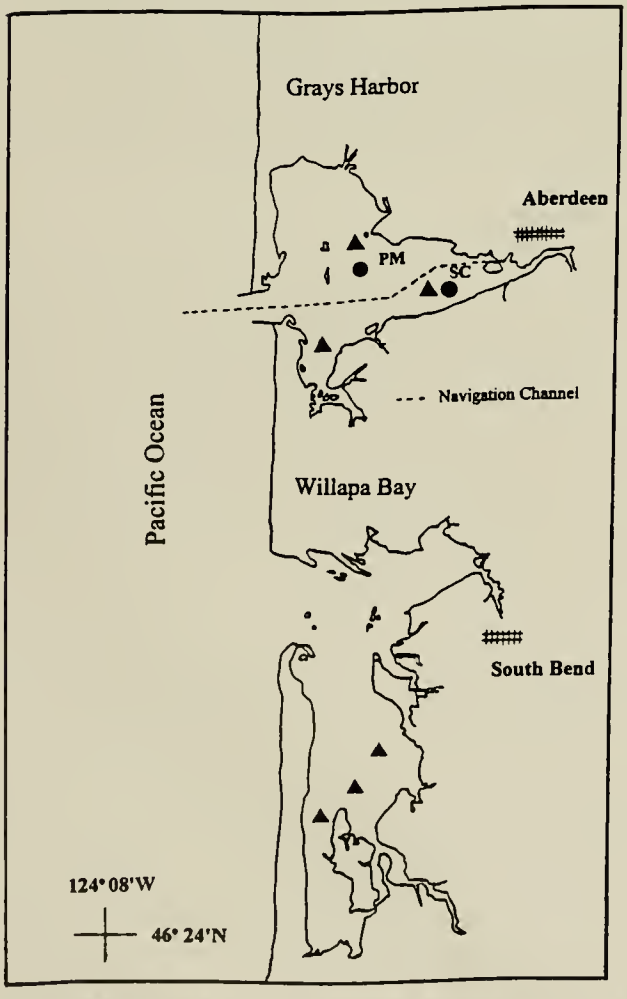

Figure 1. Map of Grays Harbor and Willapa Bay, Washington, showing locations of large-scale shell mitigation plots at Pacman (PC) and South Channel (SC) in Grays Harbor (●) and three smaller plots in Willapa Bay (▲).

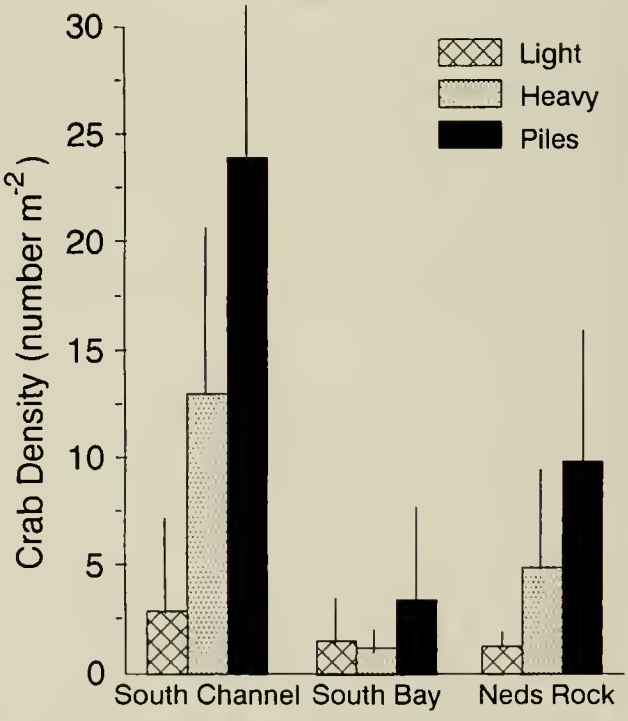

Figure 2. Time averaged (May–September) 0+ crab density (± 1 SD) in light, heavy, and shell pile habitat configurations created at three locations in Grays Harbor estuary during a 1986 pilot study (adapted from Dumbauld et al. 1993).

constructed in 1990 disappeared because of shell sinking into the substrate or sedimentation, so, in a second experiment conducted in 1991, test plots (30 m × 30 m) were placed at eight intertidal locations distributed throughout the Grays Harbor estuary. Shell sank below the surface at the majority of these sites within the first 2 weeks after construction. Tests, using a very sensitive surveyor's level to determine relative elevations and produce contour maps, showed that the process most responsible was subsidence attributable to bioturbation by resident thalassinid shrimp (Fig. 3). Sedimentation occurred as well (i.e., shell remained above grade level but was covered by additional sediment), but this process seemed to be correlated with shrimp density.

Full-scale mitigation began in 1992 in Grays Harbor with construction of two large shell plots 6.7 ha and 2.2 ha at locations known as South Channel and Pacman respectively, (Fig. 1). Shell retention by August of that year was only 32% at Pacman because of relatively high shrimp density (60 burrows/m^2), and because the shrimp present were ghost shrimp (*Neotrypaea californiensis*, Dana, 1854), which cause more sedimentation than mud shrimp (*Upogebia pugettensis*, Dana, 1852) (Dumbauld et al. 1996, Dumbauld et al. 1997). Shell retention was about 70% at South Channel, where a mix of mud shrimp and ghost shrimp were present but at much lower density (20 burrows/m^2). Although remaining shell at both sites produced juvenile crab, all subsequent mitigation projects in Grays Harbor have been at the South Channel location because of better shell retention. Based on pilot study results, the USACOE predicted that shell retention would level off at 50–80% after the first 2 years (USACOE 1989); this was not realized in the full-scale mitigation project (Dinnel 1996, Fig. 4). An exponential curve fits the data, but the slope of the retention curve is site dependent. Similar studies in Willapa Bay have since linked shell subsidence directly to abundance of shrimp and the species of shrimp present (Feldman et al. in press, Fig. 4). Finally, USACOE hoped that harrowing the shell as practiced by the commercial oyster industry (Sayce and Larson 1966), might return shell to the surface and provide for additional shell life and, therefore, crab recruitment. This was to be carried out in year 4 and was projected to return surface cover to 90% of the original. Initial tests, although never quantified, indicated that harrowing would not succeed.

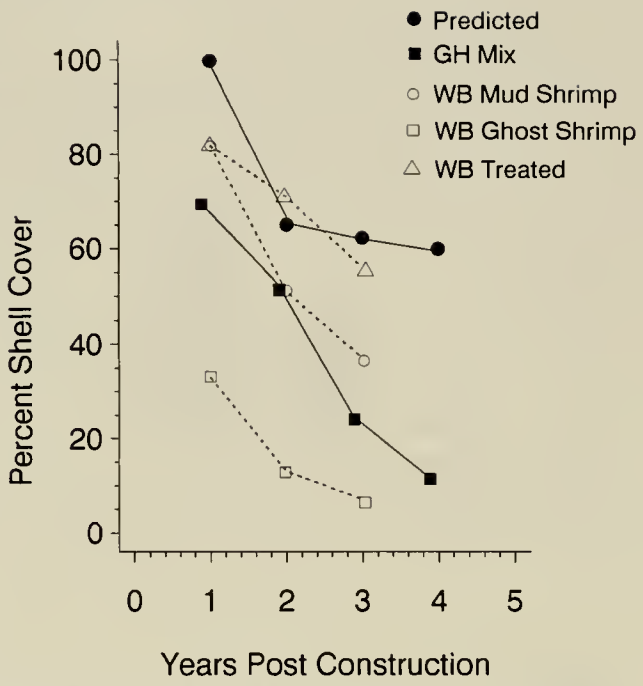

Figure 4. Shell retention over time as predicted by USACOE (●) and realized at the plots constructed in the South Channel area of Grays Harbor in 1992 (■). Both ghost and mud shrimp were present at this site. Also shown are similar retention curves for Willapa Bay at a site with ghost shrimp present (□), a site where only mud shrimp were present (○), and a site that had ghost shrimp present, but was pretreated with the pesticide carbaryl to control the shrimp (△).

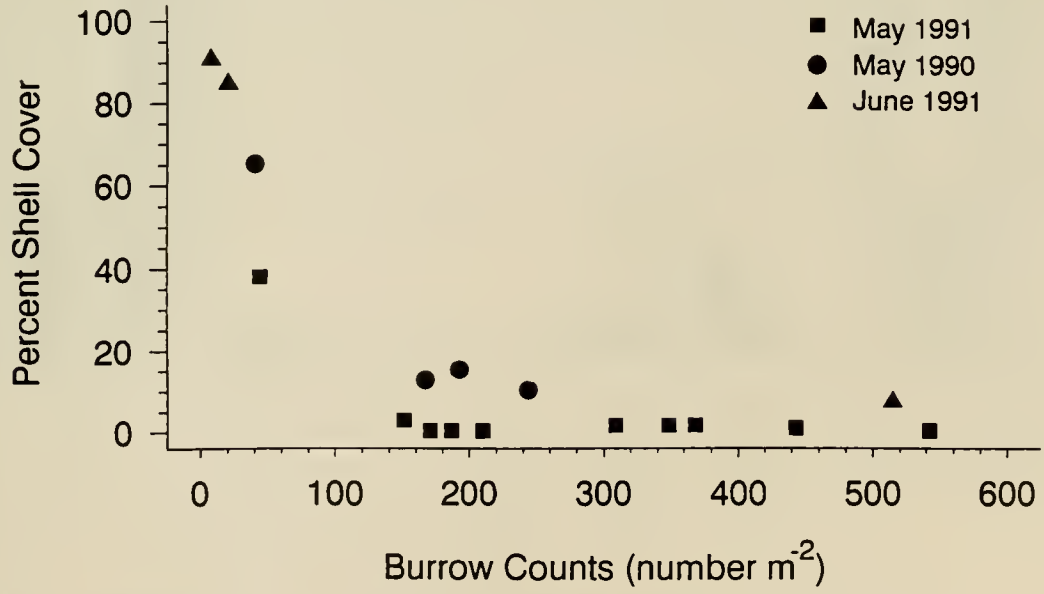

Figure 3. Relationship between shrimp burrow counts and percentage shell cover 1–2 months after deployment at 14 sites in Grays Harbor estuary. Note the significant negative correlation ($r = -0.68$, $P < 0.05$) and approximate threshold near a count of 100 burrows/m^2 above which shell retention is less than 10% (after Armstrong et al. 1992).

Faunal Composition

As part of a monitoring plan, composition, density, and/or biomass of several taxa were measured in the created shell habitat and, in some cases, compared with fauna in adjacent open mudflats. In addition to recruitment and density of juvenile Dungeness crab, two issues of interest were: (1) amount and composition of other fauna that may serve as food for Dungeness crab; and (2) the recruitment and spatial distribution of both species of thalassinid burrowing shrimp.

Certain fishes (e.g., the saddleback gunnel, *Pholis ornata*, Girard, 1854) and small crustaceans (mostly amphipods such as *Eogammarus confervicolus*, Bousfield, 1979, and *Corophium spp.*) in addition to Dungeness crab had much higher biomass (and density) in shell as compared to open mud (Williams 1994, Fig. 5). We found a relationship between the depth of shell and relative density and biomass of gammarid amphipods (up to 6,000 individuals or 4g/m^2 ash free dry weight, AFDW), but no relationship with juvenile Dungeness crab density (Fig. 6). Several important prey taxa, including juvenile bivalves and polychaetes, occurred at comparable biomass (0.7 and 0.5 g AFDW/m^2, respectively) in shell and mud (Fig. 5). The quantities of small prey suggested the resident juvenile Dungeness crab population would have sufficient food to grow and develop to an instar size (J4–J5), at which size, they emigrate from the intertidal to subtidal environment (Visser 1997). Further research indicated that predation on juvenile clams (*Macoma balthica*, L., 1758) increased in the shell habitat because of enhanced Dungeness crab abundance, holding the standing stock of clams to a similar level as that found in the open mud (Iribarne et al. 1994, Iribarne et al. 1995).

Recruitment and distribution of 0+ (young-of-the-year) thalassinid shrimp differed across the two dominant habitats in accord with species. Related to the use of shell as habitat for juvenile crab was whether shell would also reduce burrowing shrimp density and have potential as an alternative to using carbaryl to control these species that have a negative impact on oyster culture operations (Dumbauld et al. 1996, Dumbauld et al. 1997). Very high densities of 0+ ghost shrimp were found in adjacent

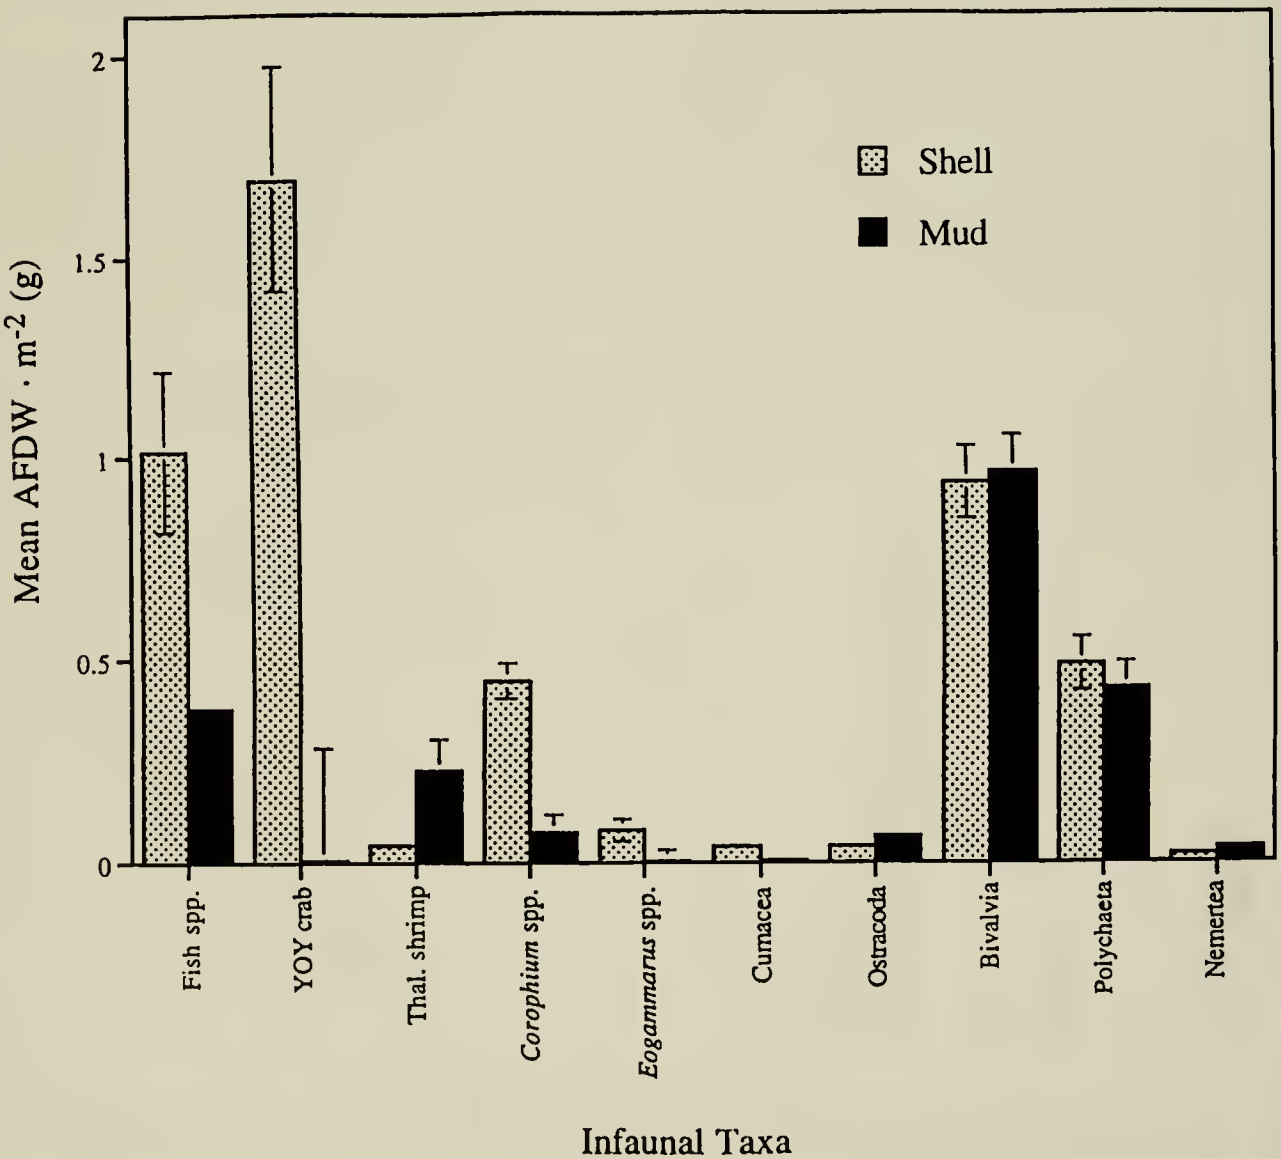

Figure 5. Mean total biomass (ash-free dry weight, AFDW)* 1.0/m^2 (±1 SE) of major infaunal taxa from shell and open mud control plots in Grays Harbor pooled across locations and months. Crab biomass estimates are based on values for J2–J3 instars (after Williams 1994).

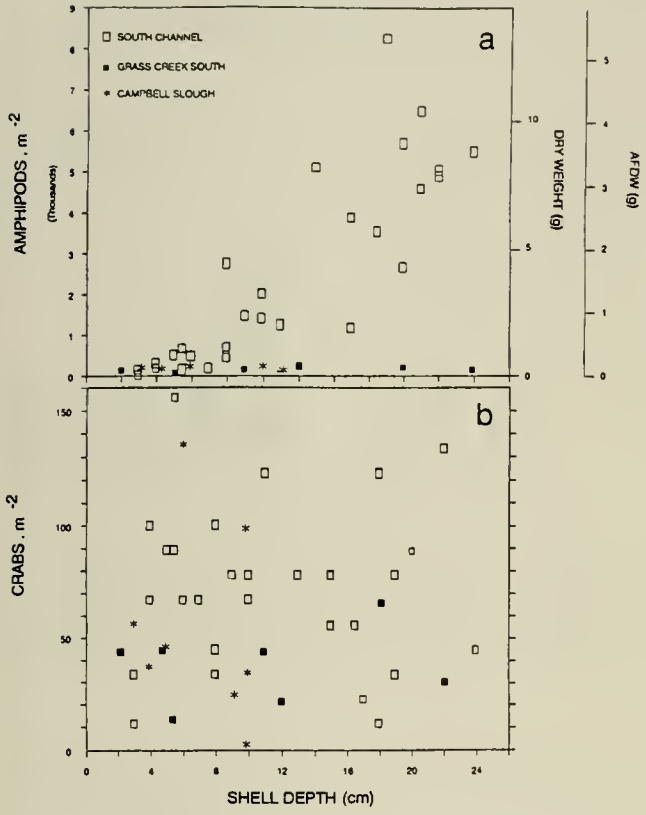

Figure 6. Amphipod and crab densities in shell samples from August 1990. A significant relationship between amphipod (*Eogammarus confervicolus*) density and shell depth is evident (A) whereas, there is no relationship between Dungeness crab density and shell depth (B). Also given is a scale for biomass (AFDW, g) for amphipods (after Armstrong et al. 1992).

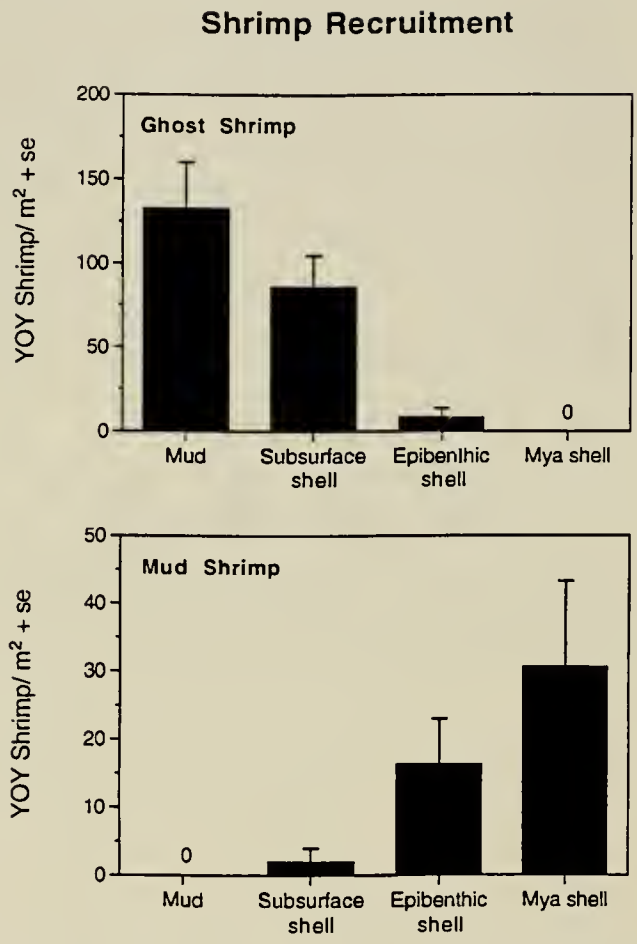

Figure 7. Number of young-of-the-year (YOY) thalassinid shrimp recruiting to open mud and various categories of shell cover, including shell that had already been buried below the surface (subsurface shell), a thick layer of oyster shell (epibenthic shell), and deposits of eastern softshell clam shells. Ghost shrimp (top) were most abundant in open mud and sand, and mud shrimp (bottom) were most abundant in shell deposits, reflecting both settlement behavior as well as timing relative to predation pressure by resident YOY crab.

open mudflat habitat and in mud overlying shell that had sunk below the surface (Feldman et al. 1997). Conversely, high densities of 0+ mud shrimp were found in naturally occurring *Mya* shell deposits and in oyster shell mitigation plots (Feldman et al. unpubl. data, Fig. 7). Feldman et al. (in press) concluded that shell generally reduces population density of juvenile ghost shrimp because of its function as a physical barrier and settlement deterrent and/or as a refuge for high densities of 0+ Dungeness crab, a predator. Mud shrimp seem less affected by surface cover of heavy shell, and, although their burrowing activity is less than that of ghost shrimp, they could pose a greater long-term threat to shell integrity.

Competition

During 1992, the initial year of shell plot construction, the abundance of Dungeness crabs that recruited to the plots was high, but few other crabs were seen. However, in subsequent years, the abundance of yellow shore crabs (*Hemigrapsus oregonensis*, Dana, 1851) found in the shell plots increased dramatically, and a negative correlation was noted between the density of these two species (Fig. 8). Further detailed investigations indicated shore crabs recruited as juveniles to the plots via larval settlement and also as adults by moving from adjacent areas (Visser 1997). Visser found the mechanism responsible for the inverse relationship between the two species of crab to be direct competition for space and not predation. Shore crabs are predominantly herbivores and scavengers, although they do consume some Dungeness megalopae. Shore crabs are very active competitors for refuge space and won an average of 78% of interspecific encounters when they were of comparable size to the Dungeness crab (Visser 1997). Because Dungeness crabs recruit to the shell on an annual basis and emigrate later at larger size to the subtidal, they are at a size disadvantage when they settle in areas where shore crabs have had time to colonize, because the latter are year-round residents. Visser (1997) also found that Dungeness crab megalopae tend to avoid settling in areas where shore crabs are present. This result was entirely unexpected and forced USACOE to reconsider the strategy of obtaining multiyear crab recruitment from shell plots that were more than 1 year old. Instead, they had to rely on new habitat construction every year.

Interannual Variability in Settlement

Dungeness crab display cyclic abundance, in part because of their pelagic larval life history, which results in variable recruitment to the benthos (McConnaughey et al. 1992, McConnaughey 1994) found a 40-fold variation in interannual settlement along the

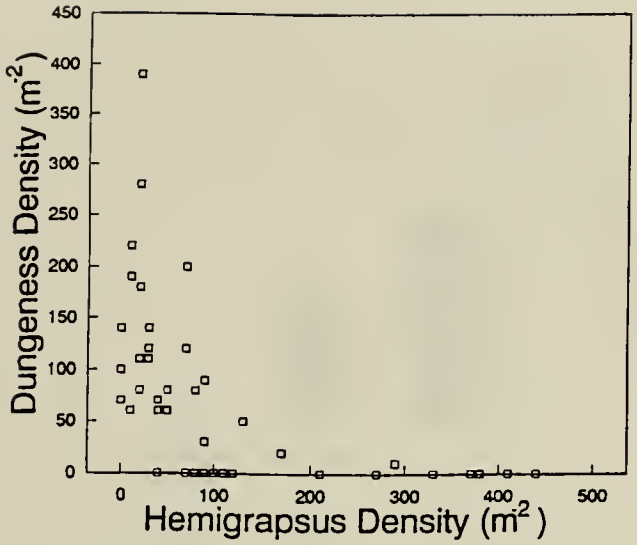

Figure 8. Density of 0+ Dungeness crab in shell mitigation plots at the South Channel location in Grays Harbor as a function of total density of shore crab (*Hemigrapsus oregonensis*) collected in the same samples from 1992 through 1994 (after Armstrong et al. 1992).

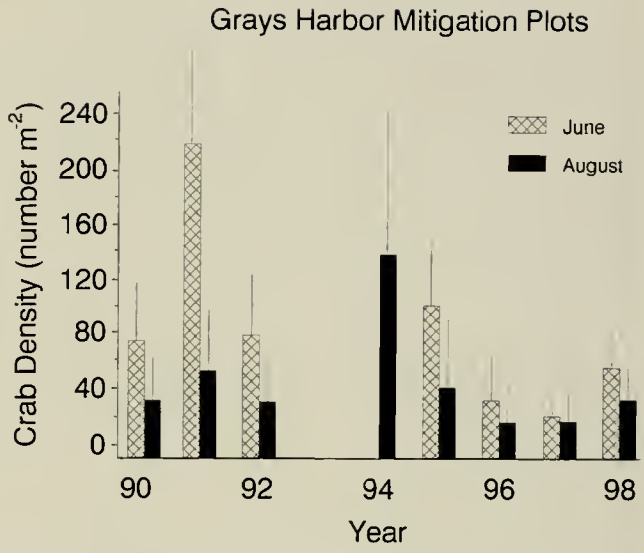

Figure 9. Average density of 0+ Dungeness crab (± 1 SD) collected in shell mitigation plots at the South Channel location in Grays Harbor from 1990 through 1998. Data were collected in 1990 to 1995 by the University of Washington and in 1996 to 1998 by Grays Harbor Community College.

Washington coast that was inversely related to the strength of alongshore and cross-shelf transport during the previous 4–5 month larval period. Crab settlement is also variable from location to location within the estuary because of wind-driven surface currents. However, Eggleston and Armstrong (1995) found that post-settlement mortality was more influential than larval supply in controlling the density of J1 instars at two locations in Grays Harbor. Density at settlement has varied substantially in the GHNIP constructed shell mitigation plot and to various other projects that have occurred since 1992 in the South Channel area of Grays Harbor; however, the average crab density in newly created shell in August was not significantly different between years (Fig. 9). Based on the results of the pilot study, USACOE chose a conservative average of 10 crab/m^2 (August) to estimate crab production for shell mitigation. This average has been met in all years, including 1992, the first year of habitat construction.

Crab Production and Dredge Entrainment Models

An adult equivalent loss model was developed to determine the number of crabs killed by dredging in the GHNIP (Wainwright et al. 1992). The model is based on a dredge entrainment function that relates the number of crabs entrained (estimated directly based on counts taken from a modified dredge) and the number of crabs present (estimated from trawls conducted simultaneously). Natural mortality estimates are used to convert different age classes of crab into adult equivalents. The model also incorporated seasonal and spatial information on crab density and size composition from the Grays Harbor estuary and USACOE dredging scenarios of gear type and amount of sediment dredged to project the number of crabs entrained and killed. The model produced an estimate of 162,000 age 2+ crab (near maturity) killed during GHNIP construction, which equates to about 73,000 3+ crab (age of recruitment to the fishery). The same mortality estimates were used to calculate the number of 0+ crabs necessary to mitigate for the loss, which came to about 9,500,000 crabs.

The original approach that USACOE took for estimating the number of 0+ crab produced by shell mitigation was based on the simplistic view that when crabs emigrate from the plots in July they are considered "produced." The standing stock density in August was multiplied by an estimate of the amount of shell remaining (total area multiplied by percentage shell cover) to give a production figure. This approach was later modified, and a production model developed that takes into account time, molt interval, growth, mortality, and multiple cohorts of settling crab (Armstrong et al. 1995). The model uses J2 density as a starting point and estimates mortality and growth from intertidal shell plot data. Results suggested either a J3 or J4 (last instar that inhabits the shell before emigrating) production unit could be valid, and J4 was selected by agency and USACOE biologists. USACOE recently refined all previously calculated mitigation estimates using this production model, and, in most cases, a higher estimate was obtained than that of the August standing stock method. This is thought to be primarily because of emigration, which begins before the August sampling date. The production model was updated and improved again based on 1998 field data showing initial settlement densities were extremely high, but survival rates were rather low. Additions to the production value were also made for crabs that were larger than the J2 starting point at the initial May sampling date. This accounts for settlement that can occur (to a minor extent) as early as March to April in Grays Harbor. Thus, the production model takes mortality rates for J2–J5 crab for each shell plot sampled and applies them to measured field density of each instar over the average time that instar spends at size before molting. This value is multiplied by the total habitat available for each month and summed to give the total number of 0+ crabs produced per plot.

SOLUTIONS AND PROSPECTS

Since 1995, an interagency work group has met to evaluate and update the USACOE crab mitigation program, and most recently, the agencies signed a strategy agreement (USACOE et al. 1998). The revised crab mitigation strategy is intended to update the Dungeness crab avoidance and mitigation measures outlined in the

original Environmental Impact Statement written for the GHNIP (USACOE 1982) in order to keep the program relevant to USACOE, the project sponsor, and agency concerns. It addresses a number of the factors listed above, including:

1. a renewed focus on and credits for avoidance of impacts, including reduced over-all dredging, a re-examination of clamshell dredging, and timing of downstream dredging to avoid peak months of crab abundance;
2. a commitment to shell mitigation for impacts remaining from past dredging and for any future impacts;
3. use of the production model (Armstrong et al. 1995) to calculate the number of young-of-the-year crab "produced" by the shell mitigation plots; and
4. continued efforts to promote impact avoidance to re-evaluate crab mitigation efforts, including semiannual meetings of the crab mitigation workgroup.

Finally, we introduce a project that attempts to mitigate for the loss of crab resulting from a test dredging project in Willapa Bay, Washington (Dumbauld and Kauffman 1999). This project represents a new twist in the mitigation strategy, because it attempts to create a living oyster reef as habitat for juvenile crabs. USACOE conducted test channel dredging on the sand bar at the mouth of Willapa Bay in August 1997 to determine the effectiveness of a new tool (agitation dredging with sidecasting) in this environment. A fairly small amount of material was removed (61,164 m^3). Bottom trawls for crabs were conducted, and USACOE agreed to mitigate for the loss of 1,931 crabs (age 2+). Given the potential for future mitigation projects in Willapa Bay, the crab workgroup used this mitigation project to determine whether techniques applied in Grays Harbor would work equally well in Willapa Bay. A second and perhaps more relevant goal for this work group was to investigate whether living oyster reefs could be created, because oysters spawn and set naturally in this estuary. The shell mitigation project was conducted in the Washington State oyster reserves in Willapa Bay. The reserves offered several advantages, including: (1) the Washington Department of Fish and Wildlife manages the reserves to protect and preserve oyster resources and, therefore, they offered an optimal site for examining creation of living oyster reefs; (2) the reserves are located in areas that typically receive larval oyster set; and (3) because oyster production is an existing activity on the reserves, permitting was simplified.

Approximately 2,567 bushels (90 m^3) of oyster shell were placed at each of three separate intertidal locations on the reserves to examine both crab and oyster recruitment in 1998 (Fig. 1). Shell placement sites were carefully selected to avoid areas with high thalassinid shrimp density; shell retention was approximately 65% in the first year. Crabs recruited to all three shell plots, but numbers were higher on the two plots located closer to the mouth of the estuary. Using the production model (Armstrong et al 1995), combined recruitment to all three plots was calculated to be about 147,000 J4 crab, which satisfied the mitigation requirement. Oysters recruited to the shell plots in late summer 1998 and began to form visible live oyster reefs in 1999, particularly at the station closest to the estuary mouth, where they were more abundant and grew faster. Crab recruitment was also highest at this location in 1999, but was markedly lower than the previous year. We hope to continue to monitor these plots to assess the value of the habitat provided by living oyster reefs as the oysters mature.

This is a brief overview of what has been and continues to be an interesting, but sometimes arduous process to mitigate for lost resources. One additional factor, not mentioned so far, is cost. Dinnel (1996) calculated that the cost of placing shell has increased since the inception of the project to the point where each crab, worth approximately $3 to the fisher, now costs USACOE at least $70 to replace through shell mitigation. With some of the refinements noted above, he notes this might be reduced by 50–60%; however, it is clear that avoiding impacts in the first place is still the most cost-effective tool. To the extent possible, USACOE and the other agencies involved have acknowledged this in the latest mitigation strategy (USACOE et al. 1998) by embracing creative steps to avoid crab loss as well as refining models to estimate crab production within shell. The cost–benefit ratio may be enhanced even further should it be possible to create living shell reefs that function as crab habitat beyond the initial year of construction as well as providing other ecosystem services.

ACKNOWLEDGMENTS

Funding for the studies reviewed here was provided by numerous sources, including the Seattle District, U.S. Army Corps of Engineers (contract to David Armstrong DACW67-85-0033 and to Brett Dumbauld at WDFW, DACW67-98-M-0255), Washington Sea Grant (contract to David Armstrong NA36RG0071-01), the Willapa Bay/ Grays Harbor Oyster Growers Association, and the Western Regional Aquaculture Center. Thanks to Loren Coen and Mark Luckenbach for the invitation to attend and present this work at ICSR and the Seattle District, U.S. Army Corps of Engineers for providing funds to do so. Finally, thanks to myriad colleagues, students, agency employees, and others, too many to list, who have been and continue to be integral components of these projects.

ABSTRACT Restoration of degraded oyster reef habitat generally begins with the addition of substrate that serves as a reef base and site for oyster spat attachment. Remarkably, little is known about how substrate type and reef morphology affect the development of oyster populations on restored reefs. Three-dimensional, intertidal reefs were constructed near Fisherman's Island, Virginia: two reefs in 1995 using surfclam (*Spisula solidissima*) shell and six reefs in 1996 using surfclam shell, oyster shell, and stabilized coal ash. We have monitored oyster recruitment and growth quarterly at three tidal heights (intertidal, mean low water, and subtidal) on each reef type since their construction. Oyster recruitment in 1995 exceeded that observed in the two subsequent years. High initial densities on the 1995 reefs decreased and stabilized at a mean of 418 oyster/m^2. Oyster settlement occurred on all reef types and tidal heights in 1996; however, postsettlement mortality on the surfclam shell and coal ash reefs exceeded that on the oyster shell reefs, which remained relatively constant throughout the year (mean = 935 oysters/m^2). Field observations suggest that predation accounts for most of the observed mortality and that the clam shell and coal ash reefs, which have little interstitial space, suffer greater predation. Oyster abundance was consistently greatest higher in the intertidal zone on all reefs in each year studied. The patterns observed here lead to the preliminary conclusion that the provision of spatial refugia (both intertidal and interstitial) from predation is an essential feature of successful oyster reef restoration in this region. In addition, high levels of recruitment can provide a numerical refuge, whereby the oysters themselves will provide structure and increase the probability of an oyster population establishing successfully on the reef.

KEY WORDS: oyster, *Crassostrea virginica*, habitat restoration, recruitment substrate, intertidal, Virginia

INTRODUCTION

The marked decline in oyster resources in the mid-Atlantic region throughout much of this century have been attributed primarily to increased harvest pressure, a direct consequence of ineffective resource management (Haven et al. 1978, Rothschild et al. 1994, Frankenberg 1995). Furthermore, the increased prevalence of the protistan parasites *Perkinsus marinus* ("Dermo") and *Haplosporidium nelsoni* ("MSX") (Burreson and Ragone 1996) and over-all environmental degradation have accelerated declines in oyster numbers over the last three decades. There is a general consensus that oyster reefs were once a dominant feature of much of the lower Chesapeake Bay, contributing considerable biological and geological structure to the system. Historically, oysters in this system likely affected systemwide trophic structure and water quality (Newell 1988, Ulanowiz and Tuttle 1992), while providing considerable physical structure, which, in turn, facilitated the development of diverse benthic communities. The need to restore oyster resources and oyster reefs, not only for their direct harvest but also for the ecological services they provide, has been recognized recently (Lenihan 1996, Coen and Luckenbach in press, Coen et al. 1999).

To date, efforts to restore the resource have been focused in areas where the oysters were abundant and extensive but have been reduced to subtidal "footprints" of former reefs. Restoration attempts carried out in areas previously devoid of oysters (as described herein) have been few. Typically, restoration of a degraded oyster reef has involved the addition of substrate to serve as a reef base and site for spat attachment and subsequent oyster growth. Oyster shell resources and/or the funds to purchase them are often in limited supply; therefore, the interest in evaluating both how to use oyster shell most effectively and the efficacy of using alternative substrates as reef bases is considerable. Attention has recently been given to the importance of vertical relief of reefs on oyster growth, survival, and disease dynamics (Bartol and Mann in press; Lenihan et al. 1996, Lenihan and Peterson 1998); however, there remains a paucity of information on the degree of relief necessary to maximize oyster settlement, recruitment, and subsequent survival. Furthermore, numerous studies have investigated the use of alternative substrates to oyster shell (Soniat et al. 1991, Haywood and Soniat 1992, Haywood et al. in press). These studies have generally been laboratory or small-scale field experiments and have not clarified how these substrates might be used to maximize oyster recruitment, growth, and survival in the context of large-scale reef restoration. These issues have increasing relevance as restoration efforts proceed throughout the extensive range of the eastern oyster. This report focuses on a large-scale field experiment in the lower Chesapeake Bay, Virginia, which related oyster recruitment, growth, and survival to reef substrate types and tidal height. The results have relevance for the choice and placement of materials and the development of design criteria for oyster reef restoration.

SITE DESCRIPTION

The study site is located near Fisherman's Island, Virginia, U.S.A., in the vicinity of the mouth of Chesapeake Bay (Fig. 1). This is a polyhaline site with a tidal amplitude of approximately 1.25 m. Marsh islands, intertidal flats, and subtidal bottom within the area are all owned by the Commonwealth of Virginia and the

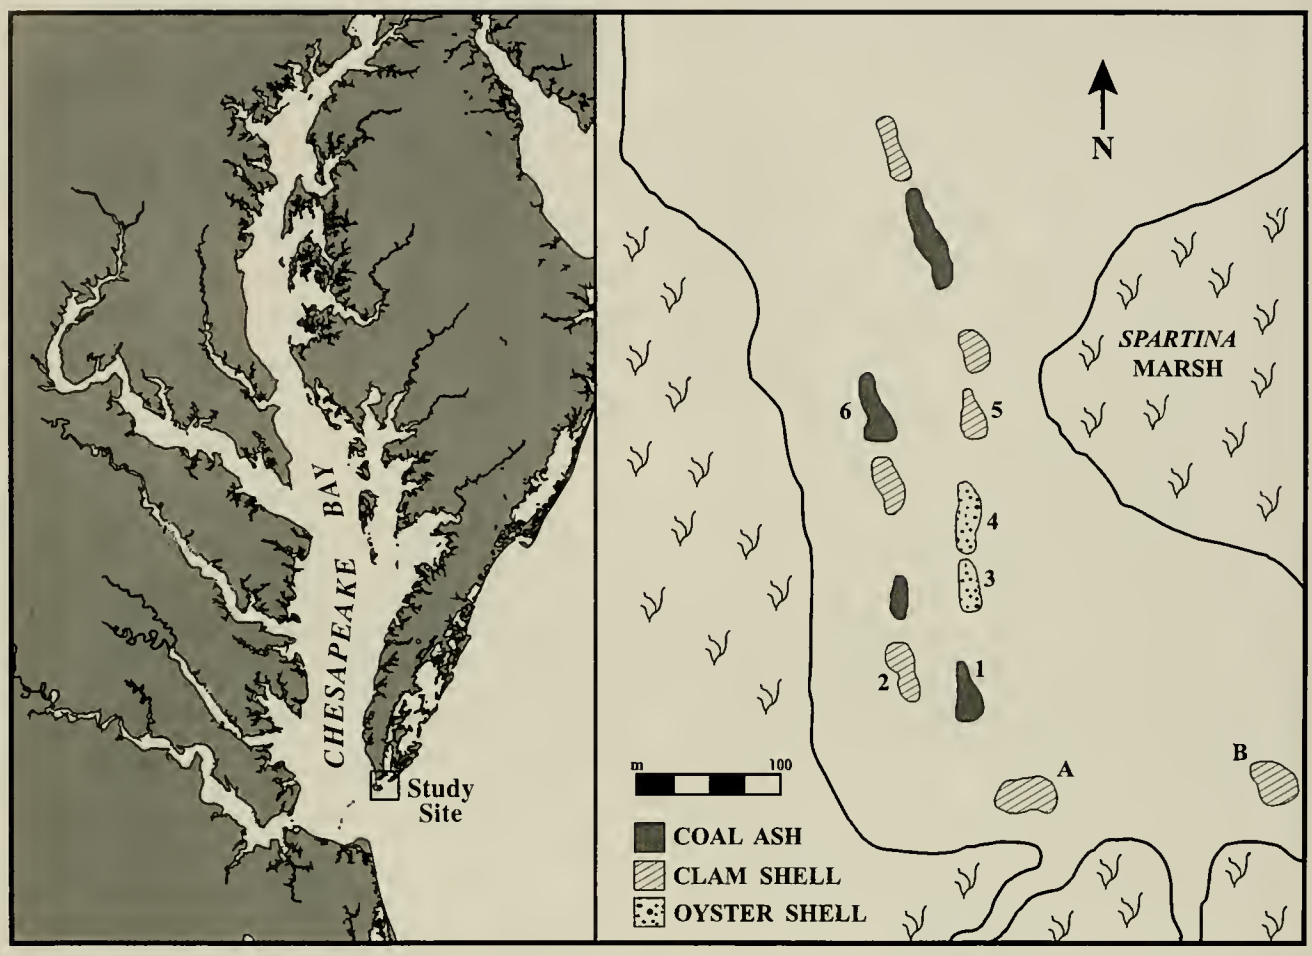

Figure 1. Location of study area near Fisherman's Island, Virginia. Reefs with an alphanumeric label were monitored continually throughout the period of the study. Reefs are not drawn to scale.

federal government and are managed by the U.S. Fish and Wildlife Service as part of the Eastern Shore of Virginia National Wildlife Refuge. In April 1995, two intertidal reefs, approximately 8,000 m^2 (2 acres) each, were constructed at the site as part of a remediation project funded by the Chesapeake Bay Bridge Tunnel District. The reefs were created by placing approximately 40,000 Virginia bushels (~ 1,973 m^3) of surfclam (*Spisula solidissima*) shells on two intertidal mudflats (see A and B in Fig. 1). The reefs extended from ~ 0.5 m below to 0.5 m above MLW. The reef designated A in Figure 1 had greater surface area at higher tidal elevation than reef B. Irregular patterns of mounds, ridges, and furrows existed across the reef surface as a result of the planting technique (deployment from barges by water cannon). Hereafter, the clam shell reefs, constructed in 1995, are designated as 95 Clam reefs.

Eleven additional reefs (Fig. 1) were constructed in 1996 with funding from the Aquatic Reef Habitat Program, Virginia Power Company, and the Virginia Oyster Repletion program. Five of these reefs were constructed with surfclam shells, two with oyster (*Crassostrea virginica*) shells, and four with stabilized coal combustion by-products (fly ash). The latter material, constructed using 88% fly ash stabilized with 12% (w:w) Portland cement, is described in greater detail in Andrews et al. (1997) and has been shown to provide an environmentally suitable substrate for oyster settlement and growth (Alden et al. 1996). Limited availability of oyster shells resulted in the smaller number of reefs (n = 2) constructed with that material. A total of 39,920 bushels (1,965 m^3) of surfclam shells, 7,000 bushels (325 m^3) of oyster shell, and 20,150 bushels (994 m^3) of coal-ash pellets were used to construct the reefs. Two reefs of each substrate type, ranging in size from 162 to 364 m^2, were selected for monitoring (reefs 1–6 in Fig. 1). The reefs were oriented in a north–south direction, with seven reefs in one row and four reefs in another row to the west. A channel ranging in width from 10 to 40 m separates the two rows. Hereafter, the reefs constructed in 1996 are designated as Oyster, 96 Clam, and Ash.

MATERIALS AND METHODS

Quadrate Sampling

Sampling of the reefs for determination of oyster abundance and size was initiated in October 1995. On each of the reefs selected for monitoring (two of each substrate type: A, B, and 1–6 in Fig. 1), quadrate samples (n = 3) were collected from each of three tidal heights. The tidal heights were 0.25 m below mean low water (hereafter called Subtidal), at mean low water (hereafter called MLW), and 0.25 m above MLW (hereafter called Intertidal). Replicate quadrates (0.0625 m^2; n = 3) were placed haphazardly within each tidal height stratum (Subtidal, MLW, and Intertidal) on replicate reefs (n = 2) of each reef substrate type

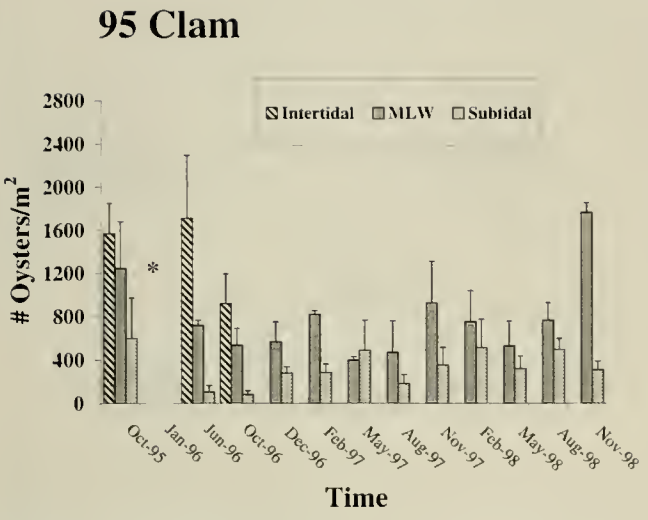

Figure. 2. Oyster abundance (number per m^2, mean ± SD) from three tidal heights throughout the study on the 95 Clam shell reefs. * No replicate quadrates were taken during this sampling period.

(Oyster, 95 Clam, 96 Clam, and Ash) to give a maximum of 72 samples per sampling period. Within each quadrate sample, all reef substrate was retained to a depth of 15 cm but did not include underlying sediments if encountered. Samples were transported to the laboratory on ice (if necessary) and were processed immediately. Processing involved the enumeration of all live oysters in each sample. In addition, 50 oysters from each tidal height, on each reef sampled, were measured to the nearest 0.1 mm. Sampling took place on a quarterly basis in an attempt to detect seasonal changes in oyster abundance.

Interstitial Space Estimates

The volume of interstitial space for each of the substrates used to construct reefs in 1996 was estimated using subsamples of the substrates before the deployment of the substrates. All of the subsamples used were considered the ideal for that substrate type: whole (with some partially fragmented) oyster and surfclam shells and ash pellets ≈ 5 cm in diameter. Interstitial volume was calculated using the volumetric displacement of the substrate packed to the top of a container (≈5.85 L). This displacement value was then subtracted from the container volume to give interstitial volume. All interstitial volumes were corrected to reflect the substrate type within a 1-L container. This process was carried out five times for each substrate in order to generate mean and standard deviation values. These values were then compared using a one-way analysis of variance ANOVA.

Statistical Analysis

The 95 clam reefs were not compared statistically with the 1996 reefs because of the dual confounding effects of temporal difference in deployment and considerable differences in surface areas of the reefs. Summary statistics generated for oyster densities and sizes by reef type are reported in graphical form.

Over the course of the study, some tidal height strata on some of the 1996 reefs were much reduced as a result of settling and/or erosion, thus we were unable to complete sampling from all tidal heights for the duration of the study. Therefore, for the purpose of comparing the abundance of oysters by substrate, we confined our analysis to the subtidal samples, for which there is a complete set of samples. Abundances were log transformed [ln (x+1)] to conform to normality assumptions as required. A two-way ANOVA was carried out (with substrate type and time as the main effects) to ensure that there was no interaction term. Upon satisfaction of this criterion, a randomized complete block design ANOVA was conducted using substrate type as the main effect blocked by time (Sokal and Rohlf 1981, pp. 345–352). The 96 Clam reefs had returns from all tidal heights for all time periods bar one (one reef in November 1997). Therefore, we were able to compare oyster abundances from all tidal heights of the 96 Clam reefs. The values from these tidal heights were compared accordingly. The Oyster reefs had complete returns from the MLW and subtidal samples for the two replicate reefs, resulting in valid comparisons of these tidal heights blocked according to time.

RESULTS

At the initial sampling of the 95 Clam shell reefs in October 1995, high oyster numbers were recorded at all tidal heights (Fig. 2). The intertidal samples had the highest oyster numbers throughout, followed by the MLW and subtidal samples, respectively. Subsequently, oyster abundances declined precipitously at all tidal heights. By November 1996, the elevations of the reefs were reduced through subsidence, compaction, and/or erosion to the point that intertidal samples could not be retrieved (Fig.2). Despite some fluctuations, the numbers of oysters on these reefs tended to remain stable in the following sampling periods. Throughout this period, the abundance of oysters remained fairly constant, mean values for the MLW and subtidal samples were 834 oysters/m^2 and 345 oysters/m^2, respectively. There were no appreciable differences in size distribution among the tidal heights through the sampling periods. Therefore, the size frequencies from each tidal height within each sampling period were pooled, and these are graphically represented in Figure 3. A unimodal population distribution is apparent for the first year of the monitoring (October 1995 to September 1996). Following a small recruitment event in December 1996 (Fig. 3), a bimodal population distribution was evident. Between August 1997 and November 1997, mortality among larger animals and an influx of small, newly recruited individuals was apparent. Thereafter, the size distribution on these reefs remained relatively stable, with small, newly recruited individuals dominating in terms of over-all abundance (Fig. 3).

Relatively low numbers of oysters were present in the Ash reef samples from December 1996 through August 1997 (Fig. 4). In November 1997, the young-of-the-year animals were detected on the reef and increased the over-all number of oysters sampled. The recruitment event in each year sampled was followed by a rapid decline in the numbers of oysters found on the reefs. Also, throughout the sampling of the Ash reefs, the intertidal stratum consistently contained higher oyster densities than the other tidal heights. The MLW stratum for the most part, had greater oyster densities than the subtidal stratum. The size distribution of oysters on the ash reefs was highly variable, with smaller oysters (< 25 mm) dominating throughout and larger oysters rare (Fig. 5).

The 96 clam reefs displayed patterns similar to the Ash reefs in terms of over-all recruitment patterns and abundances (Fig. 6). Again, relatively low densities were found each sampling period. Recruitment events were followed by a sharp decline in oyster densities. Intertidal stratum had greater oyster densities than the other two tidal heights in all but two sampling periods (November

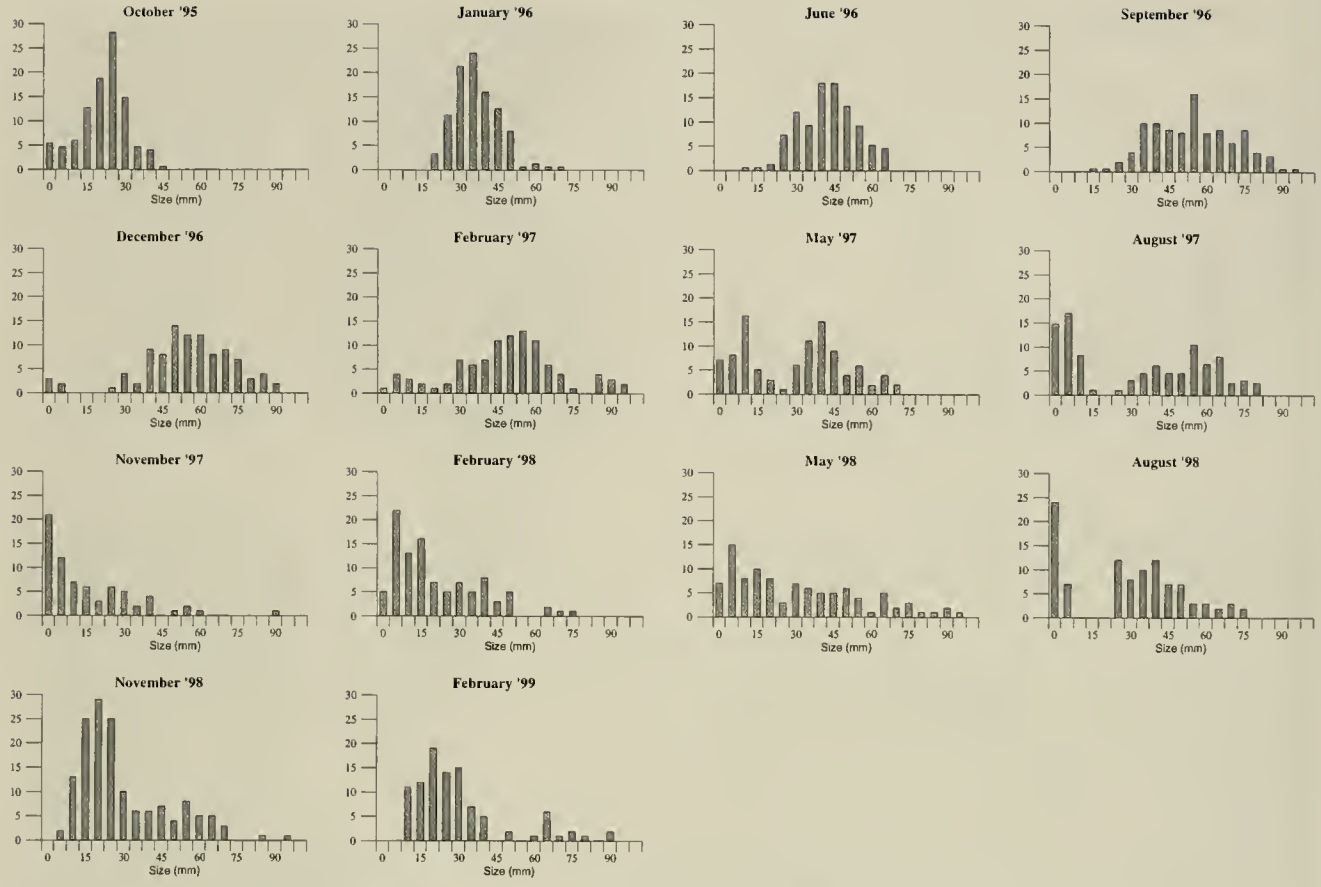

Figure. 3. Oyster size frequency distribution over the course of the study from the 95 Clam shell reefs. Size distributions were all animals combined from the three tidal heights.

1997 and August 1998). The size distributions within each sampling period was indicative of a population dominated by small oysters (< 20 mm; Fig. 7). However, in later sampling periods, there was a greater proportion (albeit small) of larger oysters on the 96 Clam reefs than found on the Ash reefs.

In 1996, in contrast to the low recruitment of oysters found on the reefs of coal ash and clam substrate, the Oyster reefs had a modest recruitment in December 1996 (Fig. 8). Survival on the oyster reef was greater than on the other substrate types, and again oyster densities were greater intertidally than at the other two tidal heights. The size distribution of oysters on the oyster shell reefs was approaching a unimodal normal distribution by May 1997 (Fig. 9). Recruitment events detected in November of subsequent years resulted in a bimodal size distribution. However, relatively large numbers of larger oysters persisted on the reefs.

Interstitial volumes differed significantly among the substrate types (Table 1). The oyster shell interstitial volume (0.7 L interstitial volume/1 L of substrate) was significantly greater than the volumes of both the clam (0.58 L) and coal ash (0.45 L) substrates. Analysis of variance of oyster densities from Subtidal samples detected significant differences among the Oyster, Ash, and Clam substrates (Table 2a). The Oyster substrate had significantly greater numbers of live oysters than the other reef types (Table 2a). The Intertidal samples from the 96 Clam reefs had significantly greater densities of oysters than the Subtidal samples (Table 2b). In addition, the densities of oysters found in the MLW samples were significantly greater than those found in the Subtidal samples on the Oyster shell reefs (Table 2c).

DISCUSSION

The reef bases at Fisherman's Island, Virginia, have all persisted, but quite different oyster populations have developed depending upon both the year of deployment and the substrate type used. Reduced elevations were observed in all reef bases, likely the result of some combination of subsidence, compaction, and erosion. Although interstitial volume estimates differed among the substrate types used on the 1996 reefs (Table 1), subsequent (mis) handling of the clam shells and large-scale production of the ash substrates (hence, poor quality control) resulted in additional compaction. These factors served to further the disparity between the oyster shell and the other substrates in terms of interstitial volume. This variation, we believe, had very significant consequences for the development of resident oyster populations as discussed below.

Oyster recruitment levels varied across the region over the duration of the study. As part of the ongoing yearly monitoring of oyster reproduction in the lower Chesapeake Bay, the Virginia Institute of Marine Science (VIMS) uses spatfall collectors (shellstrings) to determine patterns and levels of oyster recruitment (unpublished data, Virginia Oyster Spat Survey, 1970 to 1998, VIMS). During 1996 and 1997, recruitment estimated from the shellstrings at Fisherman's Island was lower in magnitude and later in each year compared with the 1995 shellstring results. This pattern was consistent with observations throughout the lower bay (Morales-Alamo and Mann 1996, Morales-Alamo and Mann 1997). Sampling on the reef surfaces was not timed specifically to record early postsettlement abundance. Other studies have shown

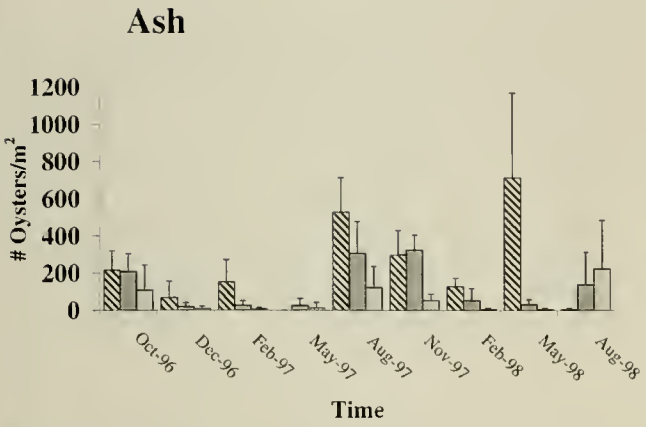

Figure. 4. Oyster abundance (number per m^2, mean ± SD) from three tidal heights throughout the study on the Ash pellet reefs planted in 1996. Legend as in Figure 2.

coal ash pellets (Alden et al. 1996, Andrews et al. 1997) and surfclam shells (Luckenbach unpublished data) are suitable substrates for oyster settlement. We would expect that early postsettlement densities, scaled to available substrate area, were comparable across reef type, but we lack confirming data.

Postsettlement survival of oysters varied in relation to tidal elevation, but the patterns were partially confounded by the loss of some tidal elevations from some reefs. The general trend observed was one of greater survival of oysters in the intertidal (Figs. 2, 4, 6, and 8), which is consistent with other studies conducted in the mid and southern Atlantic states of the U.S. (Kenny et al. 1990, Michener and Kenny 1991, O'Beirn et al. 1995, O'Beirn et al. 1996, Roegner and Mann 1995). Despite some variations in this pattern, significant differences were apparent for 96 Clam reefs, for which we have all tidal elevations present (Table 2b). In addition, oyster densities varied on the Oyster reefs between the two tidal heights evaluated (Table 2c). However, in the case of the Ash reefs, this trend was reversed on the final sampling period, with oysters virtually absent from intertidal samples (Fig. 4). These findings serve to highlight the importance of vertical relief when constructing oyster reefs in such environments as Fisherman's Island.

Variation in oyster abundance across substrate type was evident at all tidal heights (compare Figs. 4, 6, and 8), but because of missing levels on some reefs, statistical comparisons by substrate type were made only for the subtidal level (Table 2a). The significant trend of greater abundance of oysters on the Oyster reefs compared to the Ash reefs and 96 Clam reefs at this tidal level was evident throughout. Over-all mean density on the Oyster shell reef ($935/m^2$) exceeded that on the 96 Clam shell reef ($149/m^2$) and the Ash reef ($141/m^2$) roughly sixfold. Visual comparisons of the reefs are even striking. The Oyster shell reefs supported an uninterrupted layer of live oysters, which was not apparent on the other substrates, both of which had only sporadic clusters of oysters. In addition, the clam shell and coal-ash pellets reefs mostly retained

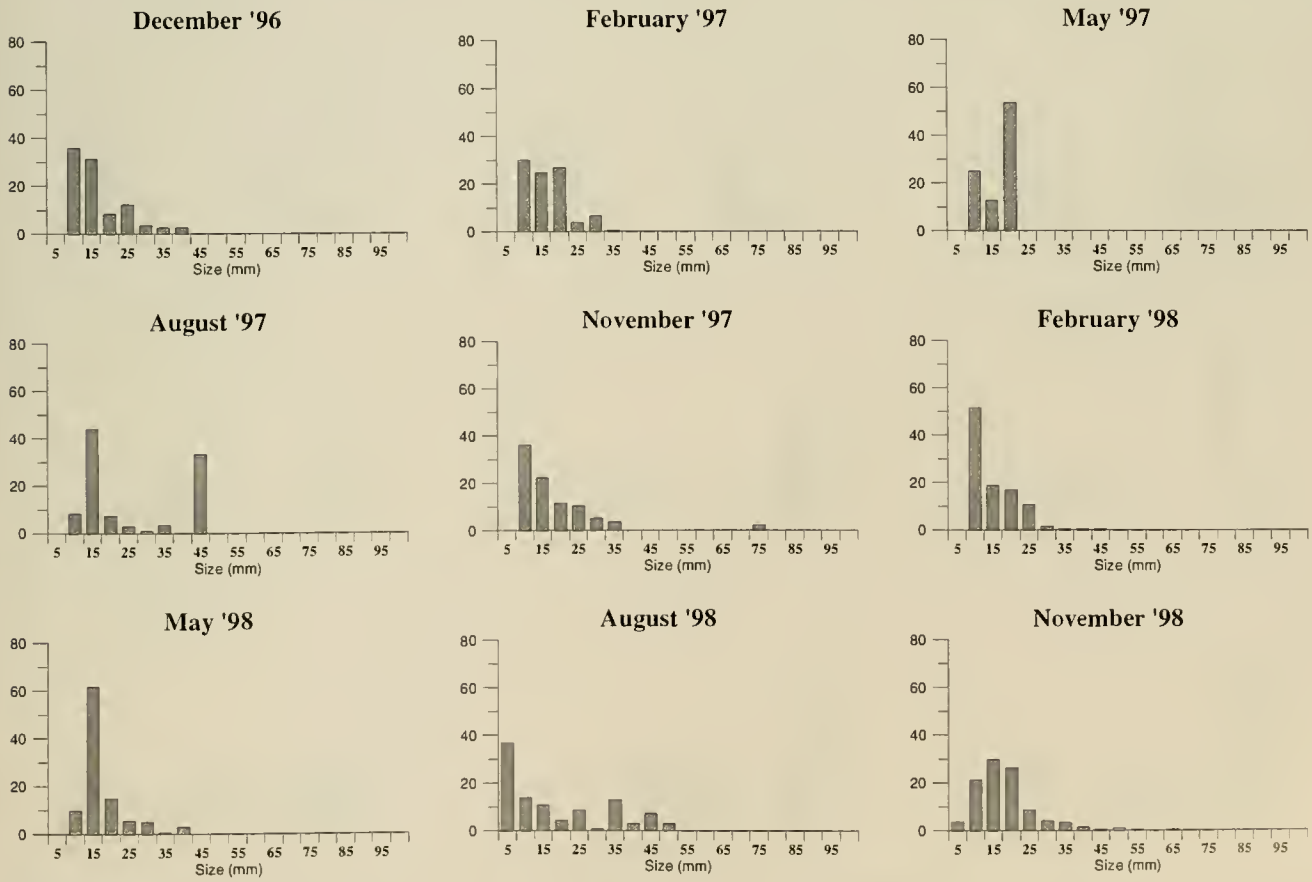

Figure. 5. Oyster size frequency distribution over the course of the study from the Ash reefs planted in 1995. Size distributions were all animals combined from the three tidal heights.

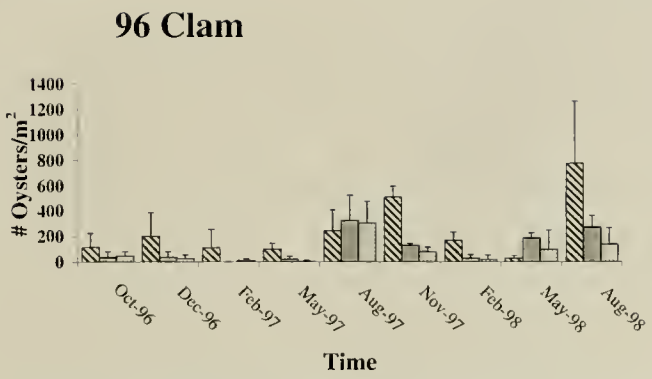

Figure. 6. Oyster abundance (number per m^2, mean ± SD) from three tidal heights throughout the study on the 96 Clam shell reefs. Legend as in Figure 2.

their original bleached white and dark gray colors, respectively, throughout the study, which is indicative of little or no biotic development on the reefs.

The dominance of the oyster shell substrate was further underscored when examining the size data of oysters from each of the substrate types. Small oysters (< 20 mm) dominated both the Ash and 96 Clam substrates (Figs. 5 and 7) throughout the entire monitoring period. There was no persistence of larger (older) oysters in either of these reef types. The 95 Clam reefs and the Oyster shell reefs had relatively greater proportions of larger oysters representing multiple year classes (Figs. 3 and 9). In August 1998, 22% (138 oysters/m^2) of the standing stock of oysters on the Oyster shell reefs had shell height ≥ 60 mm. This represented a substantial number of larger oysters that could contribute considerably to future reproductive events (Cox and Mann 1992) and, therefore, realizes a primary goal of the restoration efforts. In addition, the higher density of oysters resulted in a reef matrix that is likely to ensure the maintenance and stability of the valuable interstices.

We suggest that several factors related to the availability of interstitial space account for the observed differences in oyster abundance across the reefs. First, the reduced interstitial volume in the ash pellets and clam shell relative to oyster shell may have reduced the amount of surface area available for settlement. Bartol and Mann (1999) have reported oyster settlement onto shells 10–15 cm below the surface in a constructed reef in the Piankatank River, Virginia, and J. Nestlerode and F. O'Beirn (unpublished data) have made similar observations in substrate baskets buried in these reefs at Fisherman's Island. The density estimates we report here include oysters collected to a depth of 15 cm scaled to a flat surface area of the reef and do not account for subsurface area that might be available for oyster attachment. Thus, oyster settlement onto the Oyster shell reefs may have exceeded those on the Ash and 1996 Clam shell reefs. Because recruitment levels were low, however, and attachment surface was not in limited supply, it is unlikely that settlement differences accounted for most of the variation across reef type.

Differential mortality of oysters at the surface and below the

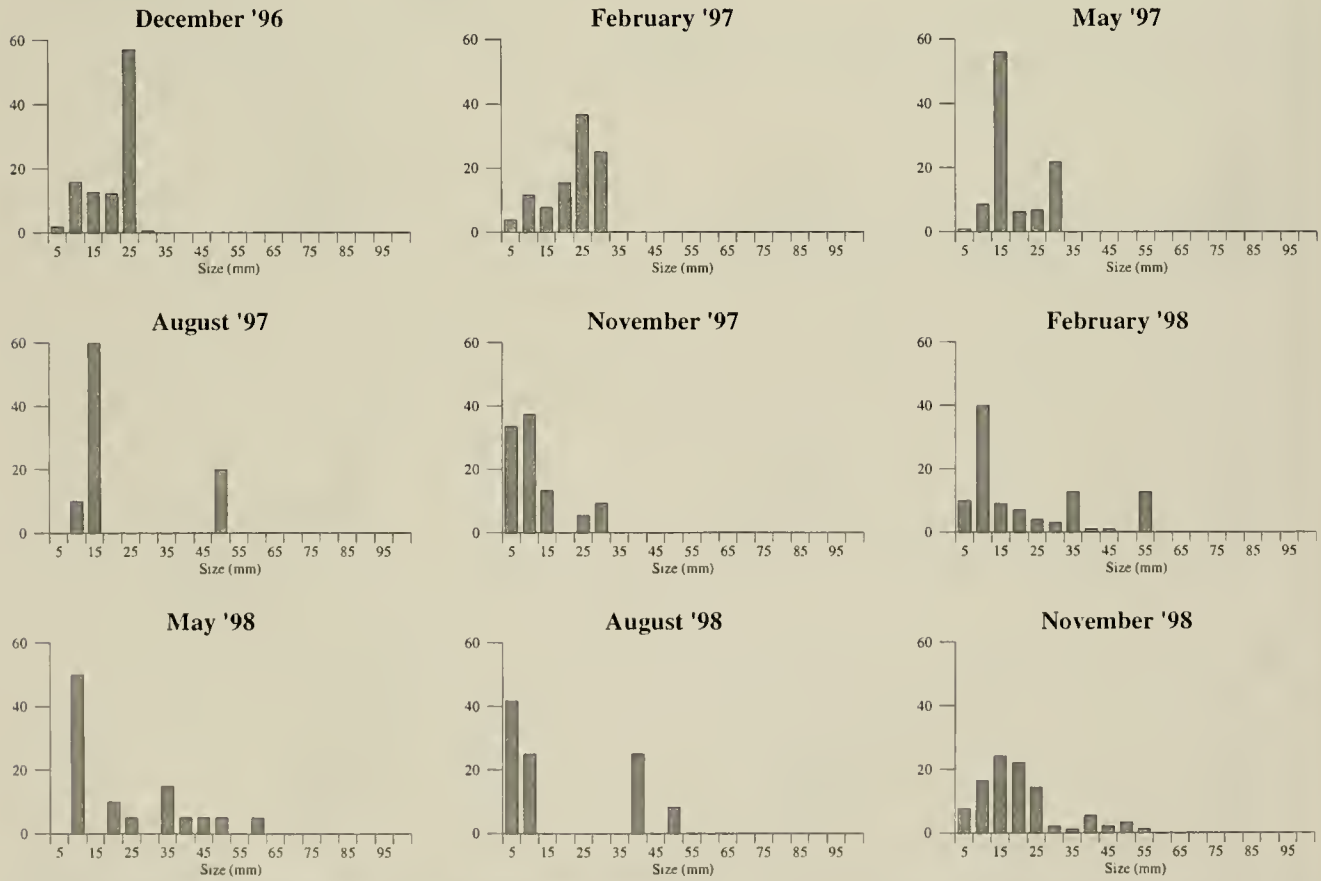

Figure. 7. Oyster size frequency distribution over the course of the study from the 96 Clam shell reefs. Size distributions were all animals combined from the three tidal heights.

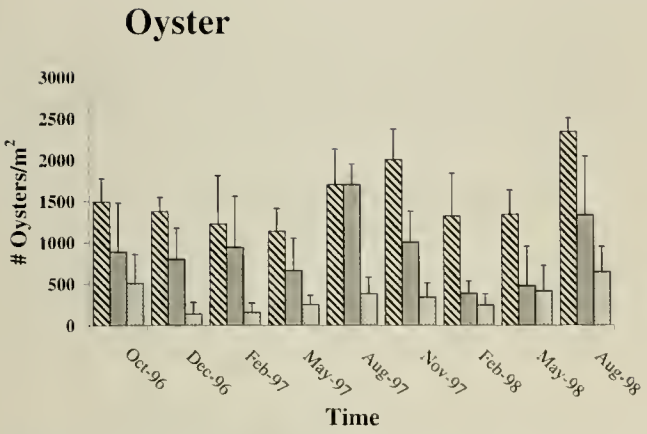

Figure. 8. Oyster abundance (number per m^2, mean ± SD) from three tidal heights throughout the study on the Oyster shell reefs planted in 1996. Legend as in Figure 2.

surface of the reefs is a likely explanation for the abundance patterns we observed. Bartol and Mann (1999) have demonstrated the value of interstitial space in aiding the survival of young oysters. The refuge afforded by the interstices protects the young oysters from predation and buffers them from climatic extremes. The considerably lower levels of interstitial space located on the clam shell and ash reefs most likely resulted in increased exposure of the young oysters to potential predators and other detrimental environmental factors (see reviews by Shumway 1996, White and Wilson 1996).

Finally, we expect a degree of positive density dependence in the development of oyster populations on constructed reefs. If the initial settlement and survival of oysters is sufficient (in part because of factors above), living oysters come to dominate the surface features of the reef and contribute to further interstitial space. In effect, the oysters themselves provide a refuge in numbers. In addition, the presence of large numbers of resident oysters in subsequent years may enhance settlement through the release of water-soluble settlement-inducing peptides (Tamburri et al. 1992, Turner et al. 1994). For example, the large recruitment event in 1995 (Fig. 2) was sufficient to result in a veneer of living oysters covering most of the clam shell substrate. Thus, when a smaller recruitment event occurred in 1996, the 95 Clam reefs and the 96 Clam reefs presented quite different habitats for new recruits and both recruitment and survival were greater on the older clam shell reefs (compare Figs. 2 & 3 with Figs. 6 & 7). Similarly, the abundances of oysters and spatial complexity of the oyster shell reefs have been increasing since their planting in 1996. Both the 96 Oyster shell reefs and the 95 Clam shell reefs developed abundant oyster densities, with multiple year classes present and reef surfaces dominated by living oysters. In contrast, the Ash reefs and the 96 Clam reefs have failed to develop abundant oyster populations, and generally only supported small size classes, which diminished in abundance after recruitment events.

Our findings suggest that in areas and years with high oyster

TABLE 2.

Results of the ANOVAs and Tukey HSD tests on (a) oyster abundance according to substrate type, (b) oyster abundance at tidal heights on clam reef, and (c) oyster abundance at tidal heights on oyster reefs.

(a) ANOVA: Oyster Abundance by Substrate Type (Subtidal Elevations Only)

Source	df	SS	F Value	*P*-Value
Substrate	2	74.39	28.09	.0001
error	43	56.94		
Tukey test:	Oyster		Clam Ash	

(b) ANOVA: Oyster Abundance by Tidal Height (Clam Shell Reefs Only)

Source	df	SS	F Value	*P*-Value
Tidal height	2	14.85	4.01	.0263
error	38	70.35		
Tukey test:	Intertidal		Mean Low Water	Subtidal

(c) ANOVA: Oyster Abundance by Tidal Height (Oyster Reefs Only)

Source	df	SS	F Value	*P*-Value
Tidal height	1	8.99	29.86	.0001
error	26	7.83		
Tukey test	Intertidal		Mean Low Water	

Tukey Test given in descending order of magnitude.

recruitment rates, the nontraditional substrates used here can serve as suitable base materials for restoring oyster reefs if mounded to provide sufficient vertical relief. In low recruitment environments, however, it is important that adequate interstitial space be present to support oyster survival. In the present study, only oyster shells provided adequate interstitial space for the development of an oyster population in low recruitment years. Given our initial concern that oyster shells are in short supply throughout much of the mid-Atlantic region of the U.S. and the unpredictable nature of recruitment in many areas, we are led to ask how to best use available substrates for reef restoration. Repeated handling of surfclam shells—from the shucking house to reef construction—seems assured of resulting in fragmentation and the tight packing on reefs described above. Mixed shell plantings using surfclam shells in combination with other shell (e.g., whelks and hard clams) may support better development of oysters by reducing compaction and increasing available interstitial space (J. Wesson, Virginia Marine Resources Commission, pers. comm). Improved quality control in the production process of coal ash pellets could result in more uniform-sized pellets, similar to those used by Andrews et al. (1997), which had a mean diameter ≈ 5 cm, provided greater interstitial space, and supported good oyster survival. Perhaps the greatest impediment to the use of coal-ash pellets in future oyster reef restoration efforts results from the U.S. Federal Highway Act of 1995, which mandated the use of recycled material in roadbed construction; thereby, changing coal ash from a waste product into a commodity and increasing its cost.

A variety of alternative substrates for oyster settlement have been tested in other studies including slate (Haven et al. 1987), expanded shale, shredded tires (Mann et al. 1990), gypsum, *Rangia cuneata* shells, limestone, concrete, and gravel (Soniat et al. 1991, Haywood and Soniat 1992, Haywood et al. 1999). Varying degrees of suitability were observed for the different substrate types. In North Carolina, limestone marl is a routinely used settlement substrate in a fishery enhancement program (Marshall et al. 1999). The applicability of these substrates for large-scale endeavors may have to be re-evaluated in light of the findings presented in this study, particularly as they relate to substrate stability and interstitial volume.

The construction of reef structures in order to promote shellfish restoration represents a significant investment of public and private resources. Developing protocols that help maximize ecological return on this investment will be important for future efforts to restore oyster reef, as will evaluating these design and construction protocols on sufficiently large spatial and temporal scales. We have observed an interaction between the substrate used in the construction and oyster recruitment levels in the development of oyster populations on large-scale constructed reefs. During periods of low natural recruitment, only substrates that provide adequate interstitial space (oyster shell in the current study) are sufficient to support the development of a viable reef. During periods of high recruitment, poorer quality substrate (i.e., that providing less interstitial space) may prove sufficient as the newly recruited oysters themselves serve as ecosystem engineers (Jones et al. 1994) providing physical refuge. In temperate, polyhaline environments, the provision of vertical relief is important in ensuring oyster survival. Again, the combination of substrate placement and oyster recruitment, survival, and growth interact to affect restoration success. Therefore, restoration design criteria (e.g., the actual configuration of interstitial space and degree of vertical relief) must account for both geophysical (e.g., siltation and ice scour) and biological (e.g., subtidal and intertidal predators) mechanisms. Given these potential constraints, we appreciate that the many factors influencing oyster survival and growth, and hence a successful start to restoration efforts, have yet to be elucidated.

ACKNOWLEDGEMENTS

The authors thank the numerous individuals that helped in the field sampling. This work was supported by the U.S. E.P.A. Chesapeake Bay Program. This is contribution no. 2288 from the Virginia Institute of Marine Science.

THE GULF COAST OYSTER INDUSTRY PROGRAM: AN INITIATIVE TO ADDRESS INDUSTRY'S RESEARCH NEEDS

JOHN SUPAN
Office of Sea Grant Development
Louisiana State University
Baton Rouge, Louisiana 70803

ABSTRACT The Gulf Oyster Industry Program (GOIP) was created in response to petitions from the Louisiana Oyster Task Force and Gulf Oyster Industry Council. These organizations initially sought long-term, research-based assistance through the Louisiana Sea Grant College Program. Subsequently, they worked with the Gulf region's Sea Grant network, the National Fisheries Institute, and the congressional delegations of several Gulf states to have the GOIP established as part of the National Sea Grant College Program in the National Oceanic and Atmospheric Administration. Implementation of this new program in a competitive funding environment necessitated reconciling two, sometimes conflicting, management goals: (1) projects having the greatest utilitarian benefits as judged by the oyster industry stakeholders; and (2) projects having the greatest scientific merit as determined by expert peer reviewers. Program development, implementation, and outcome of the first-year proposal solicitation and selection process are presented.

KEY WORDS: Gulf, oyster, research, programming

INTRODUCTION

The Gulf region leads all other regions of the U.S. in oyster production (NMFS 1998); however, the nation's total annual production of molluscan shellfish has been declining steadily. As in other areas, oyster producers in the Gulf states face myriad problems associated with (1) the presence of opportunistic bacteria, especially vibrios, in oyster-growing waters; (2) multiple-use conflicts in traditional oyster grounds, especially those associated with coastal restoration projects; (3) pollution from upstream urban and industrial development, recreational camps, and oil production facilities; (4) the depletion of harvestable stocks by oyster predators and diseases, especially the parasite *Perkinsus marinus*; (5) uncertainty about long-term stability of oyster leasing policies; and (6) declining profitability caused by declines in seasonal meat yields, a changing work force, stringent new regulations, and limited technological options.

In response to a request from the legislatively appointed Louisiana Oyster Task Force (LOTF) and the Gulf Oyster Industry Council (GOIC), the Louisiana Sea Grant College Program developed and implemented the Gulf Oyster Industry Initiative, a long-term, research-based plan to assist the industry achieve full economic recovery. In 1997, the industry successfully petitioned Congress to support the initiative with $1 million per year for 5 years. Administered by the National Sea Grant College Program, the money is to fund competitive grants through Sea Grant universities around the country. The resulting program combines the scientific knowledge of highly qualified academic researchers with the experience of industry and management agency personnel in a coordinated, comprehensive search for viable solutions to the most pressing problems of the Gulf's oyster industry. Although the Sea Grant programs of the Gulf region have supported many oyster-related projects during the last 25 years, this particular undertaking is novel in its scope, management, and the close working relationships between scientists and industry stakeholders.

The program's objectives are (1) to assist the oyster industry with needs analyses and prioritization; (2) to seek credible scientific viewpoints and responses to those needs; (3) to educate the Gulf oyster industry about the scientific status of their issues; and (4) to facilitate the development and funding of research proposals to address those issues.

APPROACH

The GOIP was designed to have continuous involvement of the oyster industry. In the program's first year, the research priorities were established by an Industry Advisory Panel (IAP) and described in the Request for Preliminary Proposals (RFP). The panel consisted of an oyster harvester and a processor from each Gulf state, ensuring that both viewpoints would be recognized. The panelists were selected by the directors of Gulf coast Sea Grant programs, with recommendations from the GOIC and the LOTF.

After preliminary proposals were received from academic researchers, the IAP determined which ones should be selected for solicitation as full proposals. The full proposals were subsequently evaluated by a Scientific Review Panel, which comprised representatives from the oyster industry, the National Sea Grant Office, and a Gulf state shellfish management agency, and scientists familiar with contemporary oyster research. This panel selected proposals for possible funding on the basis of their scientific merit and cost effectiveness, and provided a general ranking of the proposals based on peer reviews and the panelists' individual knowledge of the subject matter.

RESULTS

Primary consideration for funding was given to proposals addressing research topics previously identified as critical to the continued viability of the oyster industry. In the GOIP's inaugural year (FY 98), 18 full proposals totaling $1.1 million were solicited after a review of 35 preliminary proposals totaling $3.9 million in requested funds. Ten proposals were ultimately funded, totaling approximately $868,000. The grant recipients were from Virginia, North Carolina, Florida, Alabama, Mississippi, Louisiana, Texas, and California. The research topics and examples chosen by the IAP follow; projects receiving funding in that topic are described.

Pathogenic Organisms

A perception that the consumption of raw oysters is hazardous to public health is reducing the demand for shellstock oysters and

inflicting severe economic distress on oyster growers, harvesters, and processors. Suggested research topics include:

- develop means of treating shellstock and/or raw oyster meats to eliminate human pathogens;
- develop and evaluate strains of transgenic oysters that are capable of destroying pathogenic organisms;
- develop an international database on *Vibrio parahaemolyticus* to centralize information on the organism;
- develop depuration methods for removing vibrios from oysters; and
- develop quick depuration methods using probiotics

1998 Projects

Project Title: Use of GRAS compound, Diacetyl, for the removal of *Vibrio vulnificus* from shellstock and shucked oysters.

The objectives of this project are to determine the effectiveness of diacetyl for the reduction and/or elimination of naturally occurring populations of *V. vulnificus* within shellstock and shucked oysters and to investigate the conversion of opaque morphotypes of *V. vulnificus* to the translucent morphotype in both oyster products.

Funding level: $39,564 GOIP and $20,480 match for Year 1. $38,763 GOIP and $21,424 match for Year 2.

Consumer Attitudes and Preferences

Consumption of oysters has fallen significantly during the past decade. Lack of knowledge concerning the attitudes, preferences, and other characteristics of potential oyster consumers is perceived as an obstacle to recovering traditional markets and expanding demand for new and traditional oyster products. Suggested research topics include:

- determine oyster consumer demographics, consumption patterns, attitudes, and preferences;
- develop news media protocols for researchers and state regulatory personnel;
- develop and market-test new oyster products; and
- determine the market characteristics, including sale (i.e., region, size of establishment, average sales, etc.), distribution, and preferred product forms.

Oyster Disease

Incidences of oyster disease are rising dramatically in Gulf oyster grounds, and much of the region's oyster industry is at risk of severe economic loss through mortality of harvestable oysters. Possible research topics include:

- develop and evaluate genetic strains of oysters with superior growth and disease (pathogen) resistance; and
- develop technology to produce quantities of oyster larvae with superior growth and disease resistance adequate for commercial operations.

1998 Projects

Project Title: Predicting time to critical levels of the oyster disease *Perkinsus marinus*: A new tool for increasing oyster production.

The objectives of this project are to determine monthly levels of *P. marinus* in Galveston Bay oysters, predict the time needed to reach a critical level of disease, evaluate the reliability of the predictions, and use the information to increase oyster production by moving or harvesting oysters before they are killed by disease.

Funding level: $55,229 GOIP and $27,365 match for Year 1. $54,229 GOIP and $27,365 match for Year 2.

Project Title: Optimization of gene delivery for improved oyster health.

The objectives of this project are to compare commercial lipofection reagents to determine which is most effective; evaluate lipofection of sperm, eggs, and embryos; and evaluate the expression and function of transferred genes by disease challenging larval and adult oysters with *Perkinsus marinus*.

Funding level: $60,307 GOIP and $30,153 match for Year 1.

Project Title: Creation of an oyster cell line for *Crassostrea virginica* (Gmelin).

The objectives of this project are to produce retroviral vectors that express different reporter genes and proto-oncogenes from appropriate promoter elements in oyster cells; to optimize conditions for the infection of primary cultured cells from *C. virginica*, to infect primary cultures established from both *C. virginica* hearts and from enzymatically disrupted early embryos with the transforming retroviral vectors, to characterize the growth characteristics and phenotype of immortalized cell lines, and to test cultivation of the oyster pathogens *Haplosporidium nelsoni* and *Perkinsus marinus* in the oyster cell lines.

Funding level: $76,098 GOIP and $37,195 match for Year 1. $88,889 GOIP and $56,930 match for Year 2.

Coastal Restoration, Freshwater Diversion

Coastal land loss, deterioration of estuarine habitat, and coastal restoration programs (e.g., freshwater diversions, and sedimentation projects) are causing widespread dislocations and conflicts with established oyster-producing operations. Suggested research topics include:

- educate oyster farmers, public officials, and citizens regarding the economic role of the oyster industry and the economic costs of displacing and relocating oyster bedding operations;
- develop and test freshwater diversion and oyster farming strategies that take account of temperature and salinity conditions likely to promote fouling of bedded oysters by the hooked mussel (*Ischadium recurvum* [Rafinesque]).

1998 Projects

Project Title: The Caernarvon Freshwater Diversion Project and oyster farmers: what happened and what it means.

The objectives of this project are to describe the Louisiana oyster relocation program after recent court cases and political activity, allowing oyster farmers to make pro-active decisions about opting into the lease relocation program as it currently exists.

Funding level: $30,666 GOIP and $15,989 match: 1 year project.

Labor and Mechanization

The traditional labor base that supports oyster growing, harvesting, and processing is shrinking rapidly, with consequently declining production and increased costs. Suggested research topics include:

- investigate and develop cost-effective mechanized approaches to oyster harvesting, processing, and packing; for example, oyster shucking and harvesting machinery.

1998 Projects

Project Title: Technical and economic evaluation of a freeze-heat-cool process that facilitates oyster shucking.

The objectives of this project are to develop and evaluate pro-

totype equipment to test the freeze-heat-cool process that will facilitate shucking of Gulf oysters.

Funding Level: $61,390 GOIP and $31,000 match for 1 year.

Genetics, Hatchery Production

Seasonal monetary losses from the processing of oysters with poor meat yield hinder economic stability and growth of the industry. Some states have areas suitable for growing oysters, but these are not used because of traditional or regulatory restraints against moving seed oysters from public to private beds. These areas have high potential for oyster culture using hatchery-produced oyster seed. Suggested research topics include:

- develop cost-effective hatchery, nursery technology to augment wild oyster production by producing specialized strains; and
- address practical problems, such as fouling, predation, disease, that may be common to oyster production in general but are more acute in a farming situation.

1998 Projects

Project Title: Natural dermo resistance and its role in the development of hatcheries for the Gulf of Mexico.

The objectives of this project are to use putatively resistant broodstock from both the Gulf of Mexico and Chesapeake Bay and determine the inherent resistance of their progeny to Dermo disease to provide clear evidence for the existence of 'naturally resistant populations' of American oysters and to justify the continued development of these stocks by industry.

Funding level: $41,591 GOIP and $20,972 match for Year 1. $42,693 GOIP and $21,772 match for Year 2.

Project Title: Optimum size for planting hatchery-produced oyster seed.

The objectives of this project are to determine the optimum size of hatchery-produced oyster seed for planting on bay bottoms and to relate optimum size to costs for producing various size seed.

Funding level: $31,737 GOIP and $17,249 match for Year 1. $31,993 GOIP and $17,766 match for Year 2.

Hooked Mussel Fouling

Hooked mussel fouling on oyster growing areas has drastically increased harvesting costs by requiring the laborious removal of mussels from marketable oysters or further transplanting oysters to areas with higher salinity. Suggested research topics include:

- determine predator–prey relationships;
- determine the effects of varying haline and aerial exposures to mussel attachment; and
- determine mussel life cycle and/or recruitment.

Harmful Algal Blooms

The first reported occurrence of red tide in the central Gulf region caused a lengthy public health closure, halting production for weeks and causing severe economic hardship in the affected area. A possible research activity is to develop rapid detection methods for red tide.

1998 Projects

Project Title: Ozone-assisted depuration of red-tide-contaminated shellfish and seawater.

The objectives of this project are to determine the optimal amount of ozone needed to inactivate the brevetoxins in contaminated clams and oysters in recirculating seawater depuration tanks; determine the length of time required at the optimal amount of ozone for the desired reduction of toxins to safe levels in shellfish; and determine the effect on shelf-life of red-tide-contaminated clams and oysters subjected to such depuration.

Funding level: $52,575 GOIP and $20,307 match for Year 1. $52,575 GOIP and $20,307 match for Year 2.

Point-Source Pollution

Known point sources of pollution negatively affect certain potential oyster-growing waters, with consequent public health risks and loss of revenue to growers. Public health closures of oyster grounds in restricted areas are costly to the Gulf states in terms of lost resources, employment, and revenues. Possible research topics include:

- evaluate alternative uses of recalled oysters;
- develop a process for identifying pollution sources and linking clean-up to closure of beds.

1998 Projects

Project Title: Determination of design and operational criteria for a marshland upwelling system to treat domestic wastewater from coastal camps.

The objectives of this project are to characterize influent wastewater parameters, to determine effectiveness of a marshland upwelling system to remove fecal coliform and *E. coli* from raw wastewater, to determine the extent and movement of the freshwater plume that develops over time, and to develop an educational program for marine advisory agents and potential users.

Funding level: $78,548 GOIP and $25,569 match for 1 Year.

Project Title: Legal authority to clean up oyster beds closed because of pollution.

The objectives of this project are to examine both the applicability and inapplicability of state and federal Clean Water Act programs to compel clean up of shellfish beds contaminated by point-source pollution.

Funding Level: $30,666 GOIP and $15,989 match: 1 year project.

Black Drum Predation

Restrictions on use of gill nets as harvesting gear for finfish have enabled black drum populations to flourish, with a consequent increase in oyster predation by that species. A possible research activity is to develop novel methods of deterring black drum predation.

New Priority for FY99–00

The IAP added an additional topic for the FY99–00 preliminary proposal solicitation: economic impacts of regulatory action. The regulation of molluscan shellfish is unique compared with all other foods. Regulatory action either by state or federal public health agencies and subsequent news media responses can have severe economic impacts on the harvesting, processing, and marketing of shellfish, such as Gulf oysters. Suggested research topics include:

- analyses of de-listing of a processor or state from the Interstate Certified Shellfish Shippers List;
- analyses of inaccurate media reports on sales; and
- analyses of ramifications from product disparagement.

DISCUSSION

The scope of the projects awarded for 1998 is somewhat surprising considering the oyster industry's involvement in the program, because some of the research is basic in nature. Of the approximately $868,000 awarded for FY98–99 projects, 39% supported oyster disease research, 17% addressed oyster hatchery and genetics research, 24% investigated point-source pollution and harmful algal blooms, 7% was for labor and mechanization needs, and 3% focused on coastal restoration topics. Most surprising is that only 9% of the total awards addressed pathogenic organisms, such as *Vibrio vulnificus*, an issue perceived widely as having the greatest negative impact on the Gulf oyster industry. Despite the desperate problems Gulf oyster farmers are having with hooked mussels and black drum predation, no proposals were awarded in those categories during the program's first fiscal year. These results reflect how the GOIP solicitation and selection processes focused researchers on the industry's needs, and selecting the most highly ranked proposals based on their scientific merit.

It is apparent that the GOIP is addressing several important topics identified in earlier studies of oyster industry problems. Several of the research topics identified in the Gulf states' regional oyster management plan (GSMFC 1991) and a plan addressing the restoration of the American oyster industry (Anonymous 1990), which engendered the National Oyster Disease Program administered by the National Sea Grant Office, are being addressed by GOIP projects. The GOIP is distinguished by the way in which it addresses industry's annual needs assessment and prioritization. The greatest programmatic challenge is to fund proposals that not only address industry's needs but also have high scientific merit and educate the industry.

ACKNOWLEDGMENTS

Mr. Ronald Becker, Associate Executive Director of the Louisiana Sea Grant College Program, led the development of the Gulf Oyster Industry Initiative that was used by industry to garner Congressional support for the program. His leadership in program development, and assistance with implementation and evaluation, as well as review of this manuscript, are greatly appreciated. The review by Elizabeth Colemen is also appreciated. Many research topics from the LOTF Research and Development Committee's White Paper were incorporated into the GOIP. The GOIP would not have come to fruition without the time and effort spent by many members of the Gulf oyster industry in program development and the solicitation of Congressional support, without whose partnership this program would not have happened.

ABSTRACT Shellfish management and restoration efforts in Rhode Island date back to the late 19th century. From the late 1890s to the Second World War the Rhode Island Fisheries Commission operated a lobster hatchery in Wickford Harbor in response to a perceived decline in lobster catches in Narragansett Bay. Berried lobsters were collected, eggs hatched, larvae reared, and postlarval fifth stage juveniles were released to the bay. The project was discontinued primarily because of costs and a failure to demonstrate the efficacy of juvenile seeding in improving lobster catches. From the 1930s to the 1980s, there have been several similar efforts to establish hatcheries to produce juvenile bivalve mollusks for public and private reseeding efforts, but none of these efforts were economically sustainable. The longest running efforts to improve shellfisheries have been state programs to relay northern quahogs, *Mercenaria mercenaria*, from dense population assemblages in waters closed to shellfishing. Large-scale relays began in the 1950s in response to heavy fishing pressure but ended in the 1960s when commercial power dredging for shellfish was banned in Narragansett Bay. A small-scale state program existing since the late 1970s pays a modest fee to supervised shellfishers for hand digging quahogs in closed waters and planting them in management areas for depuration and eventual harvest. The amounts of shellfish relayed annually has varied widely since 1977, ranging between 7 and 322 metric tonnes, with an average of 98 metric tonnes per year. A new relay program has been underway since 1997. It involves assessing the shellfish stocks in the closed Providence River and hiring dredge boats to relay shellfish into down bay management areas. Based on maximum sustainable yield (MSY) considerations, annual relays should not exceed 10.3% of the standing crop (or 2721 metric tonnes) in the Providence River. An effort to restore lobsters onto monitored artificial reefs is underway using settlement funds from a 1989 oil spill in Narragansett Bay. Finally, the Rhode Island Public Benefit Aquaculture Project, a joint educational effort with commercial fisheries involvement, is involving secondary level students in the nursery culture of shellfish (though marina-based upwellers) for seeding of public shellfish beds.

KEY WORDS: Shellfish restoration, Rhode Island, shellfish relay, shellfisheries, Narragansett Bay

INTRODUCTION

Since the King Charles Charter of 1663 uniting the Rhode Island Colony of Newport to the mainland colony of Providence Plantations, there has been a codified recognition of the importance of fish and fisheries to all the citizens of Rhode Island. Although the charter is best known for its early establishment of religious freedoms, it also set forth the first principles of a public trust doctrine by entrusting the stewardship of coastal waters to the colonial assembly. All citizens were assured of free access to the waters for fishing and the collection of seaweed. In 1842 these public trust principles were incorporated directly into Article 1, Section 17 of the state constitution, and they now form the basis of all fisheries and coastal management efforts undertaken in Rhode Island's tidal waters. Nixon (1993) provides an overview and analysis of Rhode Island's public trust doctrine as it relates to shellfisheries and aquaculture in coastal waters.

The history of Rhode Island's shellfisheries can be broadly characterized as having three distinct periods. During the first period, which began in pre-Colonial times with the Narragansett Indians, shellfishing was usually a summer activity. Roger Williams (1643) the founder of Providence Plantations Colony noted that the Narragansetts would ". . . wade deepe (sic) and dive . . ." for oysters and quahogs. Shell middens found along the shore of Narragansett Bay, notably in the Potowomut area of what is now Warwick, are testament to the importance of shellfishing in the pre-Colonial era. Even the scientific name of the northern quahog—*Mercenaria mercenaria* (Linnaeus, 1754)—is testimony to the fact that the white and purple beads made from their shells were an important trading currency. From the Colonial period and early statehood until the Civil War, shellfisheries were essentially subsistence or small-scale commercial operations as authorized under the King Charles Charter or under the Article 1, Section 17 provisions of the 1842 Rhode Island State Constitution. Oysters were harvested as feed for swine and for storage as a personal food item during winter. The shells were burnt to produce lime (Kochiss 1974).

The second major period in Rhode Island's shellfisheries began with the passage of the Oyster Act of 1864 and the establishment of the Rhode Island Shellfisheries Commission. This act of the legislature allowed, for the first time, the leasing of tracts of submerged public trust lands for the purpose of cultivating oysters (Nixon 1993). The early oystermen in Rhode Island readily recognized that the waters in Narragansett Bay were very good for

growout, or maturation, of oysters (*Crassostrea virginica*). But, the seed beds in the state were not particularly productive and recruitment was very sporadic, so tons of seed oysters were brought annually into Narragansett Bay from Long Island Sound and as far away as the Chesapeake Bay (Hale 1980). This massive transplantation of oysters onto extensively managed aquaculture beds might be considered Rhode Island's first successful program of shellfish restoration, albeit the direct beneficiaries were the oyster leaseholders. In 1910, during the height of Rhode Island's oyster aquaculture industry, 8100 ha of Narragansett Bay was leased to private companies for oyster culture and 7000 metric tonnes of oysters were harvested annually (NMFS landing statistics as cited in Olsen and Stevenson 1975).

Throughout the period of massive oyster aquaculture leases in Narragansett Bay, state efforts to boost shellfish production included programs to monitor and control shellfish predators. The former Rhode Island Shellfisheries Commission and the oyster companies initiated an annual starfish census. These are reliable estimates of starfish populations in Narragansett Bay from 1880 to 1940 (Pratt et al. 1992). From time to time—when the predator populations became particularly high—there were starfish "bounty" programs (Hale 1980), and as part of regular oyster bed maintenance the oyster vessels were rigged with starfish mops similar to those still used on oyster beds in Connecticut (Olsen et al. 1980). The old-time oystermen recognized that predator control programs were a very effective way to increase shellfish production, but there was a lack of understanding that starfish could regenerate from body parts. One common practice of starfish "control" was to cut landed starfish in half and throw them overboard (Luther Blount, former President of Warren Oyster Company, pers. comm. 1993).

Beginning in the 1920s, the oyster aquaculture industry began a slow decline, culminating in a near collapse following the Great Hurricane of 1938. A number of causes have been attributed to the decline of the oyster industry in Rhode Island. These include changes in upland land uses and increased sedimentation of prime beds (Hale 1980), increased metal pollution due to a burgeoning metal-plating industry (Nixon 1995), and increased eutrophication and hypoxia in the upper reaches of Narragansett Bay due to sewage disposal (Desbonnet and Lee 1991). The Great Hurricane of 1938 was certainly a major blow to the oyster industry. Most of the shoreside docking and processing facilities were severely damaged by the storm (Olsen et al. 1980), and the recovery of the industry was hampered by the lack of a readily available workforce due to the onset of World War II (Hale 1980).

Another reason for the decline and eventual demise of Rhode Island's oyster industry may lie in the major socio-political changes that occurred in Rhode Island during the mid-1930s. In many ways, Rhode Island's oyster industry was a product of the "mill town" social system that grew up during the Industrial Revolution and the heyday of Rhode Island's textile industry in the late 19th and early 20th centuries. The oyster industry, as it was constituted, was extremely labor-intensive, very much like other industries of the era. Beginning in 1935, political shifts in the state government (known locally as Gov. T. F. Green's bloodless revolution) toward more populist policies may have had some impact upon the oyster industry. McLoughlin (1978) argued that this change in political philosophy had a profound impact on the textile industry and other industries that failed to adapt in a changing political climate.

The third period of Rhode Island's shellfisheries, reviewed by Hale (1980) and Boyd (1991), arose immediately after World War II. Many of the troops returning from Europe or the Far East in the 1940s began tonging for quahogs, largely because the old oyster beds were no longer tended and the oyster companies were not hiring. In the late 1940s the keyport bullrake was invented in the Mid-Atlantic region and was quickly introduced to Rhode Island. After several technical refinements, the bullrake became the most widely used commercial shellfishing implement by the 1960s (Boyd 1991).

The two key controversies in the shellfisheries during the 1940s and 1950s were fees paid by fishermen to oyster leaseholders for the privilege of fishing on the beds, and the introduction of power dredges for harvesting quahogs. When oyster production on the old leases declined, there was little or no effort by the state to revoke the leases and return the grounds to the open fisheries. Only after the demise of the last Rhode Island oyster company, the Warren Oyster Company in 1952 ceased culture operations, were all of the old oyster leases eventually revoked. The creation of a Coastal Resources Management Council in the late 1970s and changes in the aquaculture laws (General Laws of Rhode Island 20-10-1) in the early 1980s included provisions against aquaculturists retaining leases in public trust waters when active aquaculture operations cease (Olsen and Seavy 1983).

Throughout the 1950s and 1960s, there were countless discussions about how the quahog fishery should be managed. The main issue was whether the fishery would consist of a large number of small-scale operators using hand tongs and bullrakes or a relatively small number of operators using power dredges. The rakers and tongers argued strongly to management officials that power dredging was environmentally damaging. This prompted a number of studies, including that of Glude and Landers (1953) which showed that while dredging did allow individuals to harvest more shellfish in a shorter period of time, it was no more damaging than the cumulative impacts of large numbers of handrakers. By the early 1960s, state management officials set into statute the banning of power dredges in most of Narragansett Bay (General Laws of Rhode Island 20-6-7). Thus the strategy was to allow greater numbers of fishermen through limits on individual effort. Under this system of limiting individual effort, the fishery grew and flourished. When the Rhode Island quahog fishery reached its peak in 1985, there were an estimated 1000 full-time commercial shellfishermen, landing 2200 metric tonnes (meat weight) of shellfish, worth $15 million dockside, representing about 25% of all quahog production nationally (Boyd 1991; Pratt et al. 1992).

During the decade of the 1990s there has been a steady decline in quahog catches and a decrease in the number of active full-time shellfishermen. According to the Rhode Island Department of Environmental Management statistics in 1997, there was an estimated 500 full-time fishermen landing about 651 metric tonnes (meat weight) of shellfish. Rhode Island's national market share in quahogs has dipped to about 8%. This erosion of the fishery since the 1980s has caused concern in the industry and generated calls for means to rebuild the fishery through expanded relays, seeding, and other public aquaculture projects.

OVERVIEW

Concern about declining shellfisheries is certainly not new in Rhode Island. Through the years there have been numerous attempts to use aquaculture techniques to enhance fisheries. As previously noted, oysters were transplanted onto lease beds for maturation, but this was more of a directed private enterprise practice

on privately held lease beds. The first genuine public aquaculture for a marine species was a lobster hatchery established in Wickford Harbor in 1898 by the Rhode Island Inland Fisheries Commission in response to declining lobster fisheries (Meade 1901). As one contemporary account put it, "It is no exaggeration to say that in practically every known natural region of the North Atlantic coast, the lobster fishery is either depleted or in a state of decline" (Herrick 1909). Personnel from the hatchery would gather berried female lobsters from the Narragansett Bay trap fishery, and carefully incubate the eggs until hatching. They maintained larvae in floating fine mesh net cages and fed them a diet consisting of ground beef liver and cooked chicken eggs. While in the floating cages, larvae were gently agitated with a mechanical apparatus to keep them suspended to reduce cannibalism (Meade 1908). After reaching fourth or fifth postlarval stage, they were released into Narragansett Bay. In the first rear of lobster releases, 1901, only 9000 juveniles were released into Narragansett Bay. But in 1908, the Wickford station was releasing 400,000 lobsters, and by 1920 the facility was releasing over 1 million lobsters yearly. Peak production of the facility was in 1934 when lobster releases reached over 1.5 million (IFC 1934). The lobster hatchery program continued by the Inland Fisheries Commission (IFC) until 1935, when the agency was reorganized into the Department of Fish and Wildlife. The Wickford lobster hatchery continued under Fish and Wildlife until the 1940s (Carlson 1954). After nearly a half century of operation this remarkable pioneer program was eventually discontinued as a cost cutting measure. The site of this first state lobster hatchery is now used by the Rhode Island Department of Environmental Management's Division of Fish and Wildlife as a fisheries laboratory and a base for the patrol craft of state fisheries conservation officers.

The first Rhode Island oyster hatchery was established by Paul Galtsoff in the late 1930s at the end of South Ferry Road in Narragansett, on what is now the campus of the University of Rhode Island's Graduate School of Oceanography (GSO). The intent was to establish a facility similar to the successful oyster hatchery in Milford, Connecticut, operated by Victor Loosanoff of the Bureau of Commercial Fisheries (the forerunner of the National Marine Fisheries Service) to aid the Long Island Sound oyster industry. Galtsoff operated the hatchery for a time but it had little impact on the then moribund Rhode Island oyster industry; however, it became the forerunner of the National Marine Fisheries Service Narragansett Laboratory. The hatchery building itself remains on the GSO campus as the Mosby Center, the campus cafeteria building. The other legacy of the period is Galstoff's valuable reprint collection used as reference material in his classic (1964) treatise on the American oyster. The collection is housed currently at the nearby Pell Marine Science Laboratory.

As the quahog fisheries began to develop in the late 1940s and early 1950s, much of the quahog stocks in Narragansett Bay were located behind pollution closure lines. The first baywide wide assessment of quahogs in Narragansett Bay showed that greater than 60% of the quahogs in the bay resided in the closed Providence River and Mount Hope Bay sections of the bay (Stringer 1959). There was intense fishing pressure on the remaining open areas by both hand-diggers and dredge boats. In 1954, the Division of Fish and Wildlife initiated a shellfish relay program to dredge quahogs from the closed areas and deposit them in management areas in certified waters that would eventually be open for fishing. Between 1954 and 1968, the relay program typically moved an average of 1140 metric tonnes of shellfish annually (Table 1).

After 1968 and the banning of power dredging in Narragansett Bay, the transplant program changed character. Beginning in 1977, under the leadership of Arthur Ganz, the state-conducted relay program began paying a modest fee to supervised shellfishermen to dig quahogs and move them to the management areas in certified waters. On average over 22 y, 98 metric tonnes of shellfish were moved annually (whole shell weight; ranging from 7 to 322 metric tonnes per year). This program remains popular with the shellfishing community and has been ongoing until the present.

In spite of their popularity in the shellfishing community, the value of relay programs has long been in dispute in Rhode Island. The reluctance by state officials to dedicate permanent funding for a long-term shellfish transplant program has led to intermittent stocking attempts, primarily into already highly productive areas such as Greenwich Bay. Critics have classified the program as a "put & take" subsidized fishery, while shellfishermen contend they are denied access to highly productive areas due to long standing

sewage treatment deficiencies and argue for just compensation. Since the 1980s, shellfishermen have become dependant upon the Greenwich Bay transplant area for economic survival during the winter months. While a limited number of shellfishermen traditionally participate in transplants, hundreds of fishermen are observed harvesting upon the reopening of management areas.

Another effort to restore shellfisheries in Rhode Island included an effort by the Shellfish Commission of the Town of New Shoreham (Block Island) between 1987 and 1990 to rear hatchery seed quahogs in plastic-mesh-covered trays (Littlefield 1991). In 1989, about 120,000 *Mercenaria mercenaria* (*notata* strain) 15–20 mm in size were seeded into the Andy's Way section of the Great Salt Pond. In 1990, about 130,000 more were seeded into the same area. Littlefield (1991) reported that legal-size (about 48 mm valve length) *notata* quahogs were showing up in the 1990 fall fishery, but he did not estimate a percentage recovery rate. This project was discontinued in 1991 when Mr. Littlefield resigned from town government.

In addition to quahogs, scallops have been an important shellfishery in Rhode Island. Beginning in the early 1970s there were three major pushes to restore scallop (*Argopecten irradians irradians*) fisheries using hatchery reared seed. Scallop fisheries were historically abundant in the shallow Greenwich Bay region of Narragansett Bay and the barrier beach lagoons and estuaries along the south shore of the state (Olsen and Stevenson 1975). By the late 1960s and early 1970s, scallop catches were small and sporadic. As a result the Division of Fish and Wildlife established a hatchery for scallops at the old ferry terminal in Jamestown in 1973. The operation was moved to better facilities at the Division of Fish and Wildlife Coastal Fisheries Laboratory in Jerusalem in 1978. During its 7 y of operation, several thousand scallops were distributed to coastal barrier beach ponds. The hatchery ceased operations in 1980 for lack of continued state funding (John Karlsson, Division of Fish and Wildlife retired, personal communication 1998).

The next scallop restoration effort, in 1988–1991, was the Rhode Island Scallop Restoration Project. This effort arose in to response to massive scallop and other bivalve mortalities as a result of blooms of the picoplankton *Aureococcus anophageferens* in Narragansett Bay and coastal estuaries during the summers of 1985 and 1986 (Tracey 1988). This 'brown tide' event occurring on two successive years decimated scallop (*Argopecten irradians irradians*) populations in the coastal salt ponds and estuaries. The aim of the restoration project was to solicit funds as a nonprofit corporation and to work cooperatively with the Division of Fish and Wildlife and Spatco Ltd., a private hatchery, to hatch and rear juvenile scallops for release in the coastal ponds (Burns 1991). As a result of this collaborative project, 60,000 seed scallops (15–20 mm size) were released into Point Judith Pond in 1989. In 1990, 20,000 seed (15–20 mm) were released in the Great Salt Pond of Block Island, and 5 million seed (1–3 mm) were released into Point Judith Pond due to lack of adequate nursery facilities. Also that year, 250,000 seed (15–20 mm) purchased from a Maine hatchery were distributed to Quonochontaug, Ninigret, and Winnepaug ponds (Robert Rheault, Spatco Ltd., personal communication, 1998; Division of Fish and Wildlife records). The project was discontinued in 1991 because the nonprofit corporation could not raise sufficient funds to continue, and the intricacies of state bid-procurement regulations made advance seed orders from the private hatchery participating in the project a challenging process.

CURRENT SHELLFISH RESTORATION

Scallop

The third scallop restoration effort, the Restoration and Enhancement of Bay Scallop Populations in Narragansett Bay Project, has been underway since 1995 through the Rhode Island Department of Environmental Management Aqua Fund. The aim was to reintroduce bay scallops, *Argopecten irradians*, to areas of historical abundance in Narragansett Bay, using both hatchery-reared scallops and scallops gathered from mesh spat collector bags similar to those recently used for scallop restoration in nearby Westport, Massachusetts (Tammi et al. 1998). Seed averaging 20 mm (range 15–24 mm) was both free planted and placed in protective cages for overwintering at sites with suitable habitat. The scallops were monitored for growth, survival, and predation rates. A total of 1 million seed had been planted in Narragansett Bay as of Fall 1998, producing small sets of bay scallops in adjacent areas of some of the sites. While overall recovery of planted scallops has been minimal, several areas of the bay supported a recreational harvest of bay scallops for the first time in decades.

In 1997, additional funding was received to add scallop stocking of the south shore coastal ponds, utilizing the same methodology as the Narragansett Bay study. The coastal pond study provided control sites for comparison with the existing sites in the bay. A total of 80,000 hatchery-reared scallops were planted in the fall of 1997 and again in 1998. Growth and survival rates of scallops placed in the coastal ponds were significantly higher than at any of the sites in Narragansett Bay, despite observations of equally high predation and fouling. Additionally, populations of seed scallops have been observed in the vicinity of caged animals, as well as being found in two of the five ponds where spat collectors were deployed. The project is in its final year of monitoring and as of December 1998 there is no dedicated funding on the horizon to continue scallop enhancement efforts.

Lobster Fishery

After nearly a 50-y hiatus, there has been a revival of the idea of restoring and enhancing Narragansett Bay lobster fisheries beginning in 1996 in a cooperative study between the University of Rhode Island and the National Marine Fisheries Service (Cobb et al. 1998). Funded by restoration and remediation funds from a 1989 oil spill in Narragansett Bay, the aim of this modern effort is to increase lobster habitat, assess the survival of lobsters naturally recruiting onto artificial reefs, and assess the survival of hatchery-reared lobsters on the artificial reefs. This approach of focusing on habitat differs from the earlier approach of releasing juveniles directly into the bay without protective habitat. Six artificial reefs (10 × 20 m) consisting of either cobbles or boulders were placed in Narragansett Bay. Soft bottom and naturally rocky bottom control areas served as control areas. In 1996 and 1997, natural lobster recruitment into the areas was monitored. In 1998, about 2400 fifth stage, tagged juvenile lobsters (4.3/m^2) were released into the test sites (Kathleen Castro, University of Rhode Island, personal communication 1998). This enhancement program should run until 2001 and yield valuable data about habitat enhancement as a means for reducing predation on released hatchery-reared stock.

Quahog

In response to declining quahog fisheries in the 1990s, the Rhode Island Department of Environmental Management (DEM),

Division of Fish & Wildlife (DFW) began a population and utilization study of the uncertified shellfish resources in the Providence River (funded by a grant from the U.S Department of Commerce). Evaluating shellfish relay programs as a tool for enhancing Rhode Island's quahog fishery is essential to the development of a statewide shellfish management program. Judicious utilization of shellfish resources in uncertified waters for either relay stocking or depuration may provide revitalization of Rhode Island's shellfish industry. Project activities included a survey to determine current quahog biomass in the Providence River, calculation of estimates of maximum sustainable yields, and development of a rational plan for the transplanting of uncertified shellfish stocks. One of the key work elements of the project was a pilot project to test the feasibility of transplants. The DFW is evaluating different methodologies of transplanting for optimum benefit for the resource and the industry.

During 1997, DFW conducted shellfish dredge surveys in the Providence River to assess quahog population densities. This area had not been surveyed since 1977. The survey was conducted from onboard the 29′ R/V *Inspector Clambeaux* utilizing the same random stratified procedures pioneered in a DFW study of quahog populations in the West Passage of Narragansett Bay (Russell 1972). These techniques have been used annually since 1993 for assessing quahog populations in other areas of Narragansett Bay (Lazar et al. 1995). The Providence River stations were divided into 500 × 500 m grids and a 30-m tow was made using a hydraulic dredge. From these samples the DFW determined quahog abundance, size structure, and densities, and the maximum sustainable yield (MSY) that could be transplanted without depleting the stock. The total of 51 tows completed had a mean density of 9.37 ± (1.34 se) quahogs/m^2. Total standing stock biomass for the Providence River was 26,400 metric tonnes. The biomass was 86% top necks (60 mm valve length or larger); few sublegal or count necks were observed over the course of the survey. Subsamples of the quahogs were measured and morphometric comparisons calculated between shellfish in certified and uncertified waters. A baywide MSY was calculated using a biomass dynamic model that integrates catch per unit effort (CPUE), landings, and survey data. Data analysis indicated a maximum of 2721 metric tonnes could be removed annually from the Providence River for relay purposes without impairing stock production. For year 1 (1998), DFW recommended a minimum of 238 metric tonnes be harvested by dredge vessel for transplanting during this prototype project.

Prior to commencement of the transplant, several areas were evaluated for appropriate bottom types, existing shellfish densities and current fishing effort, predation, and proximity to depleted areas. The "High Banks" Shellfish Sanctuary was established as a management area and closed to commercial harvesting of shellfish for a period of 2 y (Fig. 1). The expectation is that this dense concentration of large adult clams will repopulate adjacent areas. The RV *Captain Bert* from the University of Rhode Island was contracted to dredge from July to November 1998. A total of 238 metric tonnes of shellfish were moved from the Providence River; all tow positions were logged using global positioning system (GPS) coordinates. Data collected onboard included tow coordinates, depth, bottom type, density, and shell measurement. These data will be utilized to update the 1997 biomass assessment. Additionally, the donor area and the adjacent highly productive "Area A" (or Upper Narragansett Bay area) will be monitored through annual dredge surveys to provide estimates of the impacts of the large-scale relays and of quahog recruitment in those areas. The

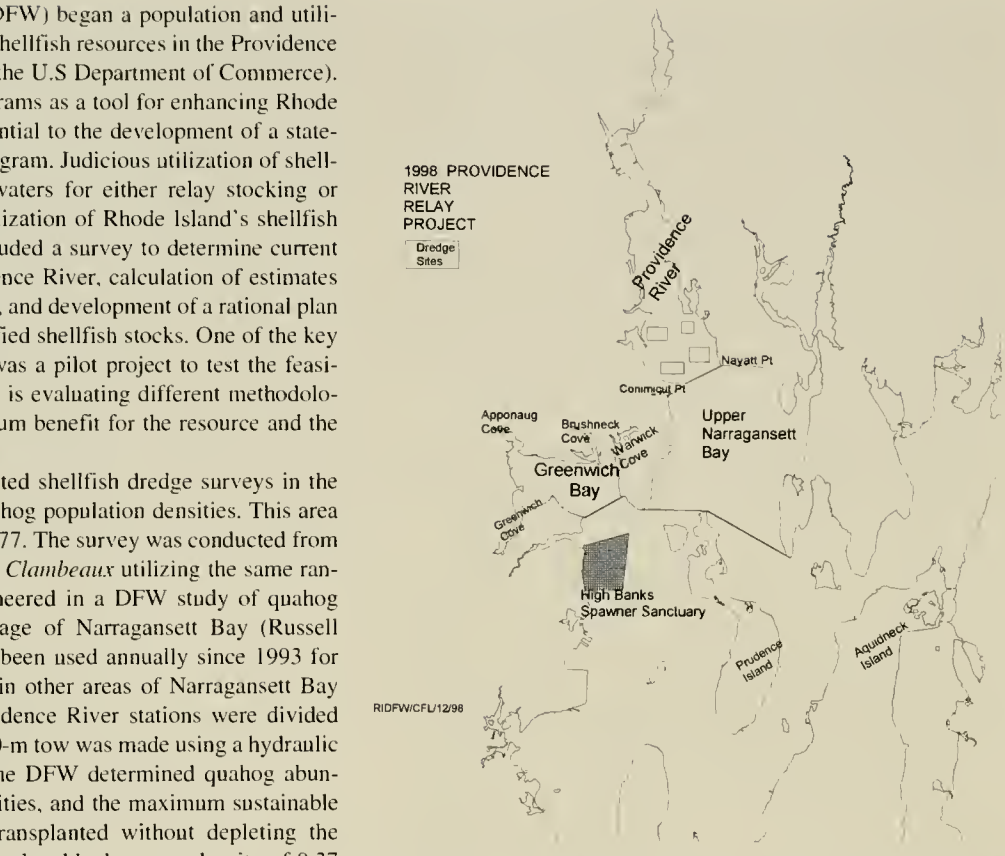

Figure 1. The source area of quahogs for the 1998 Providence River Relay Project and the recipient High Banks Sanctuary Area in Narragansett Bay Rhode Island. Also shown are the shallow coves of Greenwich Bay that serve as the source areas of quahogs for handraking relays into the Greenwich Bay Management Area.

High Banks relay area will also be monitored over 1999–2000 to address the efficacy of large-scale relays of the Providence River stock. To address recovery, growth, predation, fishing pressure, and mortality, a portion of the relayed stock has been tagged and their location logged by GPS coordinates. They will be monitored by SCUBA and DFW's dredge research vessel in 2000.

Cost analysis of the dredge relay program indicates $0.09/kg was expended to move shellfish, compared to a range of $0.08 to $0.13/kg typically expended by contracting handrakers. Expected costs for utilizing handrakers in the Providence River would likely have been well in excess of $0.13/kg, due to the added expense of daily contracting of transport vessels and the additional personnel costs for monitoring and enforcement. Also, logistically it is unworkable to provide adequate supervision of individual rakers in a relatively large area in the midst of a major shipping channel. However, contracting handrakers to move shellfish from smaller coves immediately adjacent to recipient areas appears to be an economical option, as is the case for the current Greenwich Bay relay program.

In addition to the relay efforts, there has been interest in using nursery-reared quahog seed stock for replenishing public fishing grounds. In 1996, John Williams of Warwick Cove Marina seized upon the idea of nursery culture of shellfish in marina waters (Rheault and Rice 1989) using existing floating upweller techniques (Hadley & Manzi 1984) being developed and employed by Robert Rheault of the Moonstone Oyster Company. At the incep-

tion of the Rhode Island Public Benefit Aquaculture Project, Mr. Williams' concept was to incorporate secondary education into the physical activities of raising shellfish. The project would be a means of teaching science, math, and language arts, and the product would be used to restore fishing beds in Narragansett Bay. The project, which began in 1997 with some seed monies from local foundations, had as its a mission to develop a true public benefit aquaculture project that would integrate well with current uses of the public waters of Rhode Island, without compromising the integrity or quality of the state's aquatic resources. The Rhode Island Seafood Council began assisting in the development and coordination of a team to guide this effort. The Project team realized early on that in order to be fully beneficial to the state, all stakeholders needed to be educated about the project goals.

The Project goals include:

- Strong skills-based curriculum development for secondary level education that is tied to natural resources, and the application of aquaculture principles to inject applied learning into the curriculum.
- The inclusion of commercial and recreational shellfishermen in order to build their understanding of the potential of public aquaculture to rebuild shellfish stocks, and to utilize their experience in guiding educational activities and assisting in the determination of survival of seeded stock
- The development of a self-sustaining resource restoration plan for Rhode Island incorporating aquaculture techniques to restore declining shellfish resources.

To meet the goals, a strong team of state, local, and educational representatives committed to guide the development of the Project. Initial advisors to the project were university personnel with expertise on scientific issues and independent commercial fishermen and personnel from marine trades organizations to assist in developing an economically viable plan of work that minimized user conflicts. The advisory team grew to include representatives from the following organizations:

Rhode Island Department of Labor and Training
Rhode Island Manufacturers Extension Service
Rhode Island Legislative Commission on Aquaculture
Rhode Island Economic Development Corporation
Rhode Island Department of Environmental Management
Coastal Resources Management Council
Rhode Island Seafood Council
University of Rhode Island-Department of Fisheries and Veterinary Science
Roger Williams University Center for Economic and Environmental Development
Newport, Warwick, Chariho, and Cranston Area Career and Technical Centers
Middletown Alternative Learning Program
Rhode Island Quahog Company
Warwick Cove Marina
Ram Point Marina
East Passage Yachting Center
Newport Yacht Club
The Rhode Island Shellfishermen's Association

Students from four technical high schools began building upwellers in the spring of 1998. These schools were partnered with marinas in the local area, and high school students were partnered with college-level mentors from the Marine Biology Program at Roger Williams University in Bristol. Three of the high schools built five upweller units that were deployed early summer at partner marina facilities. The five units were stocked with a total of 100,000 seed of *Mercenaria mercenaria*. Due to an unusually high rainfall in the spring, quahog seed was very difficult to obtain from local suppliers. As a result, quahog seed (2.5 mm) was purchased from Virginia after satisfying strict state importation guidelines. In addition, one unit was stocked with local oyster seed donated by the Rhode Island Sea Grant Marine Advisory Service and another unit was partially stocked with scallop seed donated by National Marine Fisheries Service Milford Laboratory.

As the quahog seed reached the presumed "predator resistant" size of 20 mm they were given to the DFW and planted in a management sanctuary had been opened for public harvest in December 1999. Current Rhode Island shellfish regulations define shellfish seed as a shell dimension of 20 mm or less for quahogs and 32 mm for oysters (RIDEM 1998). To assure public health, shellfish seed can be grown in uncertified waters of marinas, but they must be moved to certified waters for final growout and depuration once they reach the prescribed size limits. These seed definitions allow a minimum 1-y depuration period based on local growth rates.

Shellfish growth was monitored weekly by students from the partner schools and all data on growth, salinity, and temperature were recorded. As the shellfish grew students were able to apply math, science, writing, and public speaking skills to the project through presentations at their respective schools and at the Third Annual Rhode Island Aquaculture Conference, held in October 1998. This was a perfect way for students to start building a portfolio and to create a network of professional mentors. After the conference, there have been several other schools and marinas that expressed interest in participating in the project.

This collaboration has also allowed students to work alongside state biologists and to be involved in data collection for the tagging and transplant-restoration project at the High Banks Management Area being carried out by DFW. All students that have taken part in the tagging and relay-restoration effort have a better understanding of occupations within DFW, and have more direction in their education and future career choices. Additional statewide partnerships are being built: the Rhode Island Department of Health has become eager to expose students to the workings of a USFDA-certified shellfish testing lab and is making the lab available for interactive tours for the students involved in the aquaculture program.

As of December 1999 there are two proposed plans with potential to assist ongoing shellfish restoration projects in Rhode Island. One proposal is to start a commercial shellfish hatchery by the Hope Shellfish Company LLC at the Quonset Point Industrial Park, which would be partially funded from private investors, the Rhode Island Economic Development Corporation, and the Rhode Island Economic Policy Council. Part of the stated mission of the proposed hatchery is to provide shellfish seed for public aquaculture and mitigation projects in the state. The other proposal is a plan to mitigate damages caused by the January 1996 grounding of the barge *North Cape* and the devastating oil spill that resulted on the south shore beaches of Rhode Island. The National Marine Fisheries Service in cooperation with Rhode Island state agencies is proposing an ambitious multi-year plan to re-seed molluscan shellfish beds in the coastal barrier beach salt ponds and estuaries near the spill site.

CONCLUSIONS

Shellfish restoration efforts in Rhode Island have a long history. It is very instructive to examine past projects to discover the

reasons for either success or failure, and to apply these lessons to current and planned efforts. There are a number of attempted projects and a number that got started but did not prove to be sustainable in the long run. Some of the projects that have arisen out of a sudden "windfall" of funds or out of short-term public concern have been particularly susceptible to not building long-term sustainability. Some projects have flourished due to individual initiative, but failed to continue when the principals either "got tired" or moved from the area. The most successful projects in terms of longevity are those that have had perennial support by commercial and recreational fisheries clientele, local communities, and state government agencies. For successful shellfish restoration projects, there must be melding of good science, consensus on policy, public acceptance, economic feasibility, multisector cooperation, and a measure of good luck.

A cautionary note, however, is needed. In recent years there has been an increasing trend in academia and government toward collaborative, multi-agency, and multisector projects for greater cost effectiveness, sharing of talent, and sharing of resources. Although the potential benefits of collaborative multisector projects are great, there are some risks. It is short-sighted to underestimate the amount of time and effort required to bring people and organizations together and to maintain continued collaboration toward a common goal. This problem of coordination and management is not intractable; it simply needs to be recognized and planned for.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the following individuals for kindly sharing data and other information to make this review of Rhode Island shellfish restoration projects possible: Najih Lazar, Arthur Ganz, and Mark Gibson of the Rhode Island Department of Environmental Management, Division of Fish and Wildlife; Dr. Robert Rheault of Moonstone Oyster Company; Kathleen Castro of the Fisheries, Animal and Veterinary Sciences Department at URI; John Williams of Warwick Cove Marina; and Ralph Boragine of the Rhode Island Seafood Council. A PLAN FOR REBUILDING STOCKS OF OLYMPIA OYSTERS (*OSTREOLA CONCHAPHILA*, CARPENTER 1857) IN WASHINGTON STATE

ABSTRACT The Olympia oyster (*Ostreola conchaphila*) is native to the state of Washington. Once the basis for a thriving, statewide oyster industry, its numbers were drastically reduced by the mid 1940s. Water quality and overharvesting are thought to be the major factors causing its near demise. The Pacific oyster (*Crassostrea gigas*) has since replaced the Olympia oyster in Washington and world markets. Concern over the much reduced status of the stocks of native oysters led the Washington Department of Fish and Wildlife to develop a plan to rebuild them. The goal of the strategy, to restore the Olympia oyster within its historical range, is quite simple, but offers many challenges. Key elements of the draft strategy presented here include a description of the historical and current distribution, habitat requirements, and current problems associated with restoring stocks of the native oyster in Washington State. Partnering with Tribal co-managers, local commercial shellfish interests, and the general public provides new opportunities for restoring the Olympia oyster, a top priority for state management of this species. Suggested priorities for strategy implementation are also discussed.

KEY WORDS: Olympia oyster, *Ostreola conchaphila*, Washington, estuary, plan

INTRODUCTION

The Olympia oyster (*Ostreola conchaphila* Carpenter, 1857; formerly *Ostrea lurida*) is native to the Pacific coast of North America and occurs in marine waters from Bahia de San Quentin, Baja California, to Sitka, Alaska (Ricketts and Calvin 1968, Baker 1995). It primarily inhabits sheltered waters or estuaries. Once common in Washington state, the Olympia oyster now has a restricted and very patchy distribution in Willapa Bay, Grays Harbor, and southern Puget Sound.

The Olympia oyster has been the focus of human harvest for several thousand years. The Washington tribes used the oyster extensively and often based settlement locations on its harvest (Swan 1857, Washington Secretary of State 1935, Steele 1957, Elmendorf and Kroeber 1992). With European colonization, the Olympia oyster supported a large commercial industry. Olympia oyster beds in Puget Sound, Hood Canal, and Willapa Bay were harvested extensively, and later cultivated with an elaborate system of dikes (Steele 1957, Brown 1976, Westley et al. 1985). Overharvesting in the late 1800s and severe water quality problems in the 1930s to 1950s caused Olympia oyster stocks to crash, and the industry to terminate in Willapa Bay and Puget Sound, respectively.

Recent interest and concerns about the status of native Olympia oyster stocks in Washington State waters, widely recognized to be reduced from historical levels, led the Washington Department of Fish and Wildlife (WDFW) to begin developing a stock rebuilding plan. General goals of the plan are wise stewardship, maintenance of genetic integrity, and ecosystem restoration. As managers, however, we struggled with the scope of the goal statement, particularly whether or not to incorporate restoration to a level where fisheries could occur. The resulting, more generic statement we accepted, "*to restore and maintain Olympia oyster populations on public tidelands in their native range.*" defers that discussion to a later date.

STATUS OF THE POPULATION

Historical Population Size and Distribution

Historically, Olympia oyster stocks were very large in Washington State, with reported annual landings of over 130,000 bushels (4581 m^3) around 1890, principally from Willapa Bay (Townsend 1896, Fig. 1). Landings were substantially higher in the 1870s (possibly as high as 200,000 bushels), but landings were not well documented. Olympia oysters are very small so this represents a substantially greater number of individuals (approximately 1500 per bushel) than are found in current harvests of *Crassostrea gigas* (Thunberg 1793).

Within the inland waters of Washington, the Olympia oyster had a scattered distribution throughout Puget Sound and Hood Canal (Westley 1976, Fig. 1). Samish Bay once supported a large, naturally occurring Olympia oyster population, which was severely depleted in the 1800s as a result of overharvest (Brown 1976). The most abundant natural Puget Sound populations historically occurred around Olympia, primarily in Mud and Oyster bays (Steele 1957).

Current Population Size and Distribution

Native oysters are currently present on state oyster reserves in Willapa Bay on the coast, and North Bay and Case Inlet in southern Puget Sound. Dense natural sets have recently been observed in the reserves in southern Puget Sound and an annual spawning event has been noted in Willapa Bay, but very few juvenile oysters

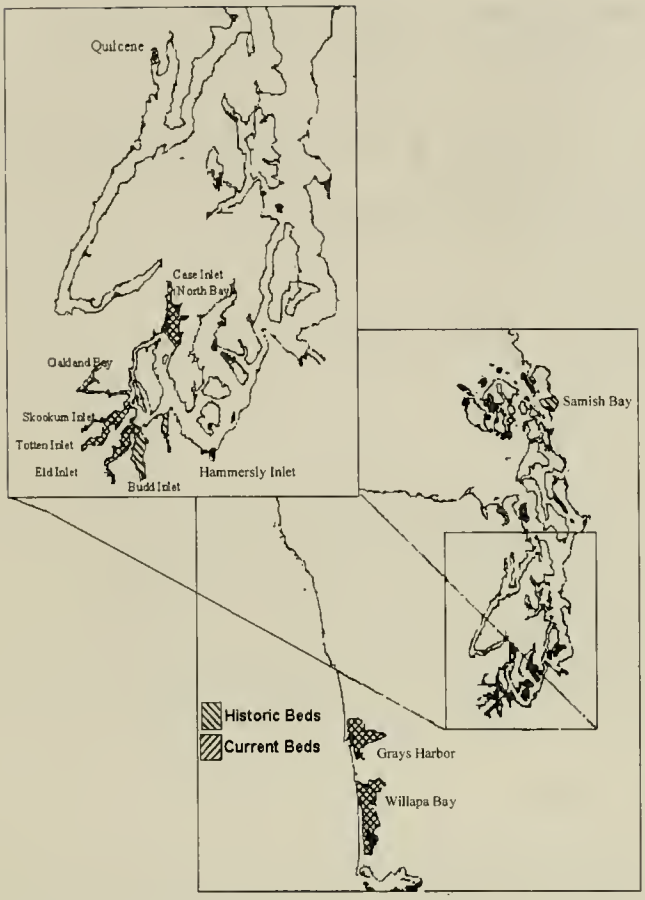

Figure 1. Map of Washington state showing the general distribution of historic and current Olympia oyster (*Ostreola concaphila*) stocks.

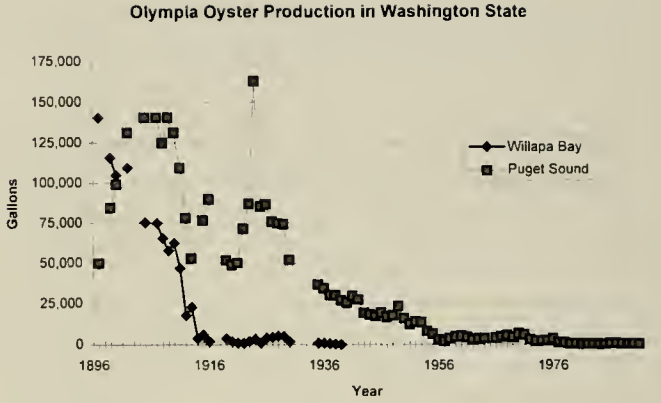

Figure 2. Olympia oyster production in Willapa Bay along the outer coast and Puget Sound in Washington State. Production in Willapa Bay declined rapidly in the early 1900s while that in Puget Sound remained higher through the mid 1930s. Production in Willapa Bay prior to 1896 was likely higher, but records are difficult to locate.

appear to have survived at the latter location. Shellfish growers in south Puget Sound had noticed similar sets in the mid 1980s, but these sets were subsequently destroyed by severe winter weather. Comparison of historical documents and local knowledge indicates that current numbers are, at best, a mere fraction of, and possibly more ephemeral than, historic populations.

Management

The Washington Department of Fish and Wildlife (WDFW) co-manages Olympia oysters with the Tribes and other government agencies in Washington state according to the provisions in the federal district court's orders and judgments (*United States v. Washington*, No. 9213, subproceeding 89-3).

Non-Tribal Commercial Fishery

WDFW harvest reports from 1897 through 1990 (Fig. 2) show a general decline in commercial production of Olympia oysters, from a high of over 200,000 gallons (757,072 L) in the early part of the century to an annual production of less than a 1000 gallons (3785 L) since 1979. Preliminary data for 1991 through 1996 show an annual commercial harvest of approximately 500 gallons (about 4000 pounds = 1814 kg of shucked oysters), most of which is from private tidelands in south Puget Sound.

Currently there are three commercial Olympia oyster growers in Puget Sound that operate solely on private tideland. The private grower controls management of stocks on private tidelands; however, Washington State Department of Health requirements must be met, and quarterly harvest reports are required by WDFW.

The Washington state oyster reserves were established in 1890 for the preservation and growth of Olympia oysters (Woelke 1969). Reserves were set aside to provide both "seed for the oyster farmer and an exploitable stock for the fisherman." At the time these laws were enacted, the typical practice in Willapa Bay was to tong or handpick the native oysters from low intertidal areas and move them to privately held tidelands elsewhere in the bay. They were held until they were shipped to markets in San Francisco, California, and Portland, Oregon. The reserves originally comprised 4548 ha in Willapa Bay and 1821 ha in Puget Sound. Some lands have since been sold by the state legislature. Reserves currently encompass 4047 ha in Willapa Bay and 405 ha in southern Puget Sound.

With the decline in the Olympia oyster population, reserve laws were changed in 1947 to reflect the growing importance of the Pacific oyster, *Crassostrea gigas*, which was imported into Washington state in the mid 1920s and rapidly established itself on reserve tidelands, particularly in Willapa Bay. Willapa Bay reserves are now actively managed for commercial harvest of the Pacific oyster. An average of 54,000 bushels (1903 m^3) of Pacific oysters are sold each year from managed intertidal tracts, as a result of which $79,000 is returned annually to the state general fund (Dumbauld and Kauffman 1996). Growers are required to return 40% of the live oyster volume in shell to the tracts to maintain stocks via natural spawning and settlement.

No commercial oyster harvest occurs on the Puget Sound oyster reserves. While Olympia oysters exist on both the Willapa Bay and Puget Sound reserves, no active management has occurred for this species, and the last commercial harvest of Olympia oysters on reserve tidelands occurred in Puget Sound in 1929.

Non-Tribal Recreational Fishery

The Olympia oyster has been managed passively on public beaches in Washington state for many years. Olympia oysters are included in the regulations that apply to all classified oysters. Current harvest limits include a combined daily limit of 18, and oysters must be shucked on the beach and the shells left at the

same place and tide height where they were taken. They may be harvested only by hand or with a hand-held manually operated prying tool (no hammers, etc.). Beginning May 1, 1998, regulations were changed for all areas except Hood Canal and the outer coast. These regulations included a minimum size restriction of 6.35 cm (2.5 inches), which was designed to minimize recreational harvesting of Olympia oysters.

All oyster reserves continue to be closed to recreational harvest of intertidal clams and oysters with several exceptions where clams and Pacific oysters may be taken. Seasons for non-reserve beaches are set based on the population and projected harvest of Pacific oysters. With the exception of one beach in North Bay, Puget Sound oyster reserves currently are not actively managed for oysters. Oyster dikes in Oakland Bay, once designed for Olympia oysters, have created excellent habitat for Manila clams (*Tapes phillipinarum*, Adams & Reave, 1850). Although the majority of the Puget Sound reserves are closed to recreational clam and oyster harvest due to access issues, these Manila clam beds do provide stock to trade with the tribes to enhance other recreational opportunities.

Tribal Commercial Fisheries
